ICE 2012 DAEGU KOREA

XXIV International Congress of Entomology

'New Era in Entomology'

August 19-25, 2012 | Daegu, Korea

ABSTRACTS

Abstracts compiled from the 24th ICE Congress website by Ohseok Kwon, Kyungpook National University. They are listed by number, in the order they appear in the Program book: Plenary talks PL1-PL6; Symposia S101M01-S1706TH06; General talks 0101M01-0703F16, and General posters PS1M001-PS7TH0478. Page numbers have been inserted (James Ridsdill-Smith, CSIRO Australia 8 March 2020).

From individuals to populations: A tale of swarms, cannibals, ageing and human obesity

Stephen Simpson
University of Sydney, Australia

There can be few more important challenges in modern biology than explaining how the phenotypic features of organisms contribute to the populations, communities and ecosystems within which they exist, and how these in turn respond to changing environmental conditions.
The phenotype sits at the confluence of influences arising from the genes and the environment and it is the phenotype which is subject to natural selection. I will use my group's work on locusts and other insects to show how spanning individuals to ecosystems can be achieved by combining theory, laboratory and field experiments and by using techniques from a range of disciplines, including molecular biology, neurophysiology, biochemistry, behaviour, mathematics, statistical physics, computer science, engineering, evolutionary theory and landscape ecology.
Locust plagues are one of the most infamous insect scourges, affecting the lives of 1 in 10 people on the planet. But they have also provided important new clues into the causes of human obesity, how we age, and the complex behaviour of crowds.
I will take us on a strange journey that begins in the midst of a locust swarm and ends with the human obesity epidemic. Along the way you will see what you can discover by ticking a locust's leg with a paintbrush, how recreational drugs turn shy solitary locusts into swarming party animals, how robotic aircraft are being used to track swarms, how statistical physics offers the key to understanding collective movement, the sinister role played by cannibalism in marching bands of locusts and Mormon crickets, and how a powerful appetite for protein can help explain not only locust mass marching but also human obesity and ageing.

Biodiversity, Symbiosis and Evolution

Takema Fukatsu
National Institute of Advanced Industrial Biology and Technology, Japan

In nature, organisms are living in close association with surrounding physical environment as well as other organisms. Thus, each of the organisms is regarded as a component of the ecosystem. Considering the diverse microbial community found inside the organisms in general, each of the organisms can also be regarded as constituting an ecosystem.
Many insects and other organisms constantly harbor microorganisms inside their body, which has been referred to as "endosymbiosis". Due to the close spatial proximity, extremely intimate biological interactions and inter-dependency are commonly found between the partners called host and symbiont. Novel biological properties are often generated through such associations. In many cases, host and symbiont are integrated into an almost inseparable entity.
Our main research targets are diverse endosymbiotic interactions found in insects. We are also interested in sophisticated biological interactions associated with such phenomena as parasitism, reproductive manipulation, morphological manipulation, animal sociality, etc. Mechanisms underlying these biological interactions are investigated by using multi-disciplinary approaches including molecular biology, genetics, physiology, ecology and evolutionary biology.
Here I present an overview of our research topics on the endosymbiosis and evolution in insects, which underpin the overwhelming biodiversity of the animal group.

Keywords:*Insects, symbiosis, bacteria, mutualism, parasitism, evolution*

Pathogen transmission dynamics at the human-mosquito interface

Thomas Scott
University of California, U.S.A.

Mosquitoes transmit pathogens that cause malaria, filariasis, dengue, yellow fever, West Nile fever, Rift valley fever, chikungunya, and many other infectious diseases that take an enormous toll on the health of humans, domestic animals, and wildlife. Efforts to prevent these diseases have been sorely tested by their resilient responses to our control efforts and the complexity of their transmission systems. After more than a century of trying to control them it is fair to ask, what are the key points where transmission is most vulnerable to operationally and cost effective intervention? How should public health policy be modified, across different spatial and temporal scales, to account for differences in the behavior and ecology of mosquitoes and humans, environmental change, and perturbations to transmission from control operations? Because it is the context in which questions like these will be answered, an improved understanding of interface between ecology and epidemiology is rich with opportunities for addressing the most important challenges in mosquito-borne pathogen prevention.

In my presentation I will explain how increasing our capacity to capture epidemiologically relevant complexity of pathogen transmission –human social interactions and mosquito ecology –will enhance disease prevention programs.Focusing on dengue, a mosquito transmitted virus, I will review the development of novel concepts in pathogen transmission dynamics that my colleagues and I are testing. I will explain why we need to expand our vision beyond the historical influence of simplifying assumptions, to explore more difficult to track variation in the rate at which mosquitoes bite different people and how human and mosquito movement influences encounters between mosquitoes and people. I will explain why exploration of mosquito ecology and behavior, mosquito and human movement, spatial heterogeneity in complex epidemiological landscapes, and the way those factors lead to key encounters between mosquitoes and hosts are among the most promising frontiers for improved mosquito-borne disease prevention.

Habitat loss and fragmentation – What happens to insect populations and species?

Ilkka Hanski
University of Helsinki, Finland

Conversion of natural habitats to cultivated fields, plantations, built areas and so forth has been and continues to be the main threat to biodiversity in general and to the viability of insect populations and species in particular. For instance, forest loss in Madagascar has caused the apparent extinction of a large fraction of endemic forest-inhabiting dung beetles and undoubtedly of many other insect taxa. I discuss with examples two key concepts which describe the responses of insect populations to habitat loss and fragmentation, namely extinction threshold and extinction debt.

Habitat conversion and other global changes, especially climate change, impose new selection pressures on populations and often lead to microevolutionary changes.

I describe examples in which demographic (ecological) population dynamics and microevolutionary dynamics are closely coupled and influence each other. Microevolutionary changes may compensate for the detrimental ecological consequences of habitat loss and fragmentation, but such compensation is likely to be only partial at best and is hence unlikely to save populations and species from extinction.

When small populations become completely isolated in small or relatively small fragments of habitat, they are likely to accumulate deleterious mutations due to inbreeding and genetic drift, which may lead to permanent loss of viability and eventually to extinction. I describe an example of such mutation accumulation in the Glanville fritillary butterfly.

Insect science and poverty alleviation – tales from Africa

Christian Borgemeister
International Centre of Insect Physiology and Ecology, Kenya

Insects and other arthropods are major threats to human health, livestock and agriculture in sub-Saharan Africa. Scientists at icipe (International Centre of Insect Physiology and Ecology) are developing novel solutions to control pests by manipulating insect ecology and behaviour. Malaria mosquitoes and crop pests can be pushed away from their hosts with repellant odours and pulled towards traps. Desert locusts, if prevented from communicating with each other, will not form swarms.
Tsetse flies can be lured into special traps where they are contaminated with the spores of their own fungal pathogens, which they then disseminate throughout their populations.
Controlling pests with these innovative tools, as well as promoting the commercial use of beneficial insects such as bees and silkworms, are just some of the ways that icipe is improving the health, food security and quality of life in African communities, providing practical and hands-on examples on how science can contribute to poverty alleviation in Africa.

Ecological Succession of Insect Populations in Bt cotton agroecosystem: a Case Analysis in China

Kongming Wu
Chinese Academy of Agricultural Sciences, China

During the last 16 years, widespread planting of transgenic crops producing insecticidal proteins derived from the bacterium Bacillus thuringiensis (Bt) has provided highly effective control of several major insect pests of cotton and corn in the World. China started to plant Bt cotton in 1997, and extended to 3.8 million hectares in 2011 that was equivalent to 70% of the national cotton-growing area of 5.7 million hectares. Continuous annual surveys of insect pest populations in Bt cotton agroecosystem since its commercialization in China suggested that the planting of Bt cotton significantly decreases the population levels of the main target pest Helicoverpa armigera not only in cotton fields but also in other host crop fields.
As a result, the applications of broad-spectrum insecticides are largely reduced in Bt cotton fields, which consequently brings a marked increase in abundance of natural enemies that in turn provide additional biocontrol services spilling over from Bt cotton fields into neighboring crops (maize, peanut and soybean). On the other hand, due to the reduced use of insecticides, Bt cotton provides a shelter for non-target pests, mirid bugs (Heteroptera: Miridae), which have progressively increased their population levels and acquired pest status in cotton and multiple other crops.
Our work demonstrated that the growing of Bt crops can bring long-term landscape-level impacts on population evolution of insect pests and natural enemies, therefore, rational/regional wide integrated pest management strategies should be developed for sustainable use of transgenic Bt crops.

Systematics, Phylogeny and Zoogeography

Changing the way we describe biodiversity

Andrew R. Deans[1], Matthew J. Yoder[2], James P. Balhoff[3], Istvan Miko[4], Katja C. Seltmann[5], Matthew A. Bertone[6]

[1]Penn State University, U.S.A., [2]Illinois Natural History Survey, U.S.A., [3]National Evolutionary Synthesis Center, U.S.A., [4]Penn State University, U.S.A., [5]American Museum of Natural History, U.S.A., [6]NCSU, U.S.A.

Taxonomists invest enormous effort into annotating phenomes and packaging these statements into 'descriptions'. These annotations - head black, femur longer than tibia, etc. - are usually published in analog resources (as per the current ICZN) and infrequently, if ever, used again. Frustratingly, the annotations are often reproduced de novo using inconsistent syntax, lexicons, and concepts, when a taxon is revised. Our vision centers on a new approach for describing taxa that employs a model developed in the biomedical and genomics realms: Entity-Quality statements (EQs) derived from phenotype ontologies. Ontologies represent a foundational technology for establishing shared semantics, and for capturing and computing with biological knowledge. In the EQ model, an entity term from an organism-specific ontology is associated with a quality term from a generic trait ontology, a compositional approach that has been shown to facilitate interoperability across scientific domains. Formalizing taxon descriptions in this way will avail millions of explicit data annually for researchers interested in adaptation, phenotypic plasticity, evo-devo, diagnostics, and other subdisciplines that focus on phenotypes. Moving towards a formalized phenotype-based system will have profound long-term consequences: 1) the terminology used to reference phenotypes will be unified across multiple realms of biodiversity research, thus facilitating knowledge transfer; 2) phenotype statements based on ontologies enable direct comparisons of trait variation across Life; 3) tying the phenoscape to genomics will allow broad-taxon retrieval of information relevant to the genetic control of phenotypes; 4) taxon concepts will be standardized, making diagnoses and species delimitation more meaningful.

vSysLab: A platform for development of monographs for the digital future of taxonomy

Norman F. Johnson
The Ohio State University, U.S.A.

To maximize its impact for the future, taxonomic works should be directed not only toward the traditional reader, but also expose their results to machine-based datamining. vSysLab is a database application designed to facilitate acquisition and management of biodiversity data and to generate output for both of these 'audiences.' The application integrates nomenclatural data, literature annotations, taxonomic concepts, and character definition. The user interacts with vSysLab through standard web-based forms accessible through any browser. The mode of character and character state definition is fully compatible with entity-quality statements and, therefore, for integration of formal ontologies (such as anatomical ontologies for morphological characters). Output options for the taxon-by-character matrix include plain-text, Nexus, Lucid Interchange Files, and text implementing the developing Structure of Descriptive Data XML standard. Full taxonomic descriptions produced by the software incorporate not only character data, but also nomenclatural history, material examined summaries, links to dynamic distribution maps, as well as free text. Summaries of taxonomic and specimen data are output implementing the DarwinCore archive format. Complete documents implement the taxpub XML schema for taxonomic publications. With this semantic markup incorporated into the final document, the information is immediately accessible for datamining as well as for automated incorporation into aggregators.

Cybertaxonomy of species rich clades using character matrices as data repositories and natural language parsing for rapid publication of species descriptions

Shaun Winterton
California State Collection of Arthropods, U.S.A.

Estimates of global biodiversity are as varied as they are enormous, but the societal need for documenting biodiversity has never been greater. The taxonomic process is as slow and careful as it is inefficient and tedious, with numerous instances of data redundancy. Natural Language Descriptions parsed from character matrices has significant promise for enhancing the process of taxonomic description to produce highly standardised taxon descriptions, coupled with the wide availability of high-resolution imaging and distributed online databases. This means that taxon descriptions can be produced rapidly in machine-readable format that is reusable and distributable (e.g. monographs, interactive keys, EOL taxon pages). A paradigm shift away from traditional handcrafted descriptions towards character matrices is required, and this 'cybertaxonomic' method holds tremendous potential for significantly increasing the output of taxonomists. Results from a recent cybertaxonomic study of species-rich genera (totalling 200+ species) of Australasian stiletto flies (Diptera: Therevidae) empirically show that hundreds of new species can be described in a timeframe far shorter than traditional taxonomic studies.

Scratchpads (http://scratchpads.eu/) are a flexible system for people to create their own virtual research environments supporting their biodiversity research activities. Scratchpads embed the process of data creation, archival and scholarly publication into a website that help users to work collaboratively by managing the increasingly complex range of tasks involved in carrying out research. As of March 2012 the project had over 6,000 active users across nearly 350 separate communities. This date also marked the fifth anniversary of the Scratchpad project and the release of a major new version of the software. This version combines technical enhancements that make the project more sustainable with new features that make the system more functional and easier to use. In this presentation we briefly review the first five years of operation, summarise recent developments and outline a roadmap for the next five years. With reference to entomological examples we show how people are using this tool to integrate their research activities, and using new analytical and publishing services to gain greater exposure for their data.

Species file software: Its past, present and the future

R. Edward DeWalt[1], David C. Eades[2], Matthew Yoder[3]
[1]University of Illinois, U.S.A., [2]University of Illinois, U.S.A., [3]University of Illinois, U.S.A.

The Species File Software development group provides software, tools, and support services to taxonomists in their efforts to catalogue and understand the diversity of life and to share the resulting data with the global community. The group is endowment supported with commitment to continued development and bug fixing well into the future. Currently 11 insect species files are supported with nearly 92,000 total names and 56,000 valid species names being shared with the Catalogue of Life, Global Biodiversity Information Facility, and several other data aggregators indirectly through CoL. Species Files is fully web functional, capturing and displaying nomenclature, literature, images, sound recordings, distribution, and specimen data Internet. New features include the use of Life Science Identifiers in all species files, the ability to produce private species files, tracking of nomenclatural history, Darwin Core Archives generation, and updated key design. In the future, we are building additional tools for taxonomists and offering services to the biodiversity and taxonomic community. We invite taxonomists to collaborate with us to build additional species files for their group of interest.

An integration of cryobanking and web-based image recognition systems for systematic studies and curation

Jer-Min Tsai[1], Wen-Bin Yeh[2], Yaw-Syan Fu[3], Mei-Ling Chan[4], Man-Miao Yang[5]

[1]Kun Shan University, Taiwan, [2]National Chung Hsing University, Taiwan, [3]Kaohsiung Medical University, Taiwan, [4]National Museum of Natural Science, Taiwan, [5]National Chung Hsing University, Taiwan

Contemporary systematics has incorporated multidisciplinary approaches and applied many technologies. As molecular and digital techniques become more accessible, the application of these data in assisting morphological taxonomy becomes popular. Collections of specimens are no longer confined in dry (pinned) or web (spirit-preserved); preservation of frozen materials has developed in many institutes worldwide. In Taiwan, the Cryobanking Program developed five years ago has preserved more than 1,300 species on various groups of insects from the participating academic institutions. Each specimen has reserved cryobank tissues accompanying its digital images. We have barcoded thousands of specimens in diverse groups, such moths, butterflies, longhorned beetles, stag beetles, midges, thrips, and many others. As cryobanked specimens have digital inventories and images available, we have developed web-based image recognition and automatically retrieval systems based on the uploaded images of various groups. Appropriate images based on the contour, pattern and/or color characteristics were extracted from general body background first and then went through the processes of normalization, computation, and comparison to the database. As diagnostic characters for different insect groups varied, it is necessary to develop specific algorithms for appropriate taxonomic category, such as family, superfamily, or suborder. Use of wing images in automatic recognition for giant silkmoths, an accuracy reaching 97% was shown. The current web-based recognition system not only plays a role as a user-friendly interface for a layman to learn the specimens on hand, but also serves as a useful tool for curation since not all the cryobanking materials have been identified.

PBI and beyond databasing and the heteropteran community

Christiane Weirauch[1], Randall T. Schuh[2]

[1]University of California Riverside, U.S.A., [2]American Museum of Natural History, U.S.A.

The Plant Bug PBI (Planetary Biodiversity Inventory) database was created in 2004 primarily to facilitate revisionary taxonomic research on Miridae (Hemiptera). This talk examines how the structure, outlets, and uses of this database have changed during the past 7 years. The PBI database now embraces multiple user interfaces and serves as central resource for several other projects funded by the US National Science Foundation on systematic research of Hemiptera and other arthropods, among them several monographs of Reduviidae or assassin bugs. The PBI database has recently undergone further changes in the context of a Tri-Trophic Databasing project (TTD Digitization Thematic Collection Network) that aims on large-scale documentation of the North American fauna of predominantly phytophagous Hemiptera, their host plants, and the parasitic Hymenoptera that exploit them. The data collected during this project will be relevant for studies of climate change, plant-herbivore-parasitoid phenology, pest status and distribution, biological control, systematics, and biogeography.

From field to screen and beyond: New methods for the collection, curation, and illustration of parasitic Hymenoptera (Insecta)

Matthew Buffington[1], Michael Gates[2]

[1]Systematic Entomology Laboratory, ARS-USDA, U.S.A., [2]Systematic Entomology Laboratory, ARS-USDA, U.S.A.

A significant portion of the 'taxonomic impediment' for parasitic Hymenoptera (Insecta) surrounds the collection of fresh material from various biogeographic regions, as well as illustrating the myriad of new species through taxonomic publications. The collection and processing of large bulk samples of arthropods is a time intensive endeavor. If the target taxa are small (1.0?5.0 mm), such as parasitic Hymenoptera, the challenge is even greater. First, we present on some techniques the we have formulated or modified that are designed to enhance the speed and efficiency by which bulk field samples can be processed. Techniques include a modified deployment system for Malaise traps, a fractionater for separating large arthropods from the small ones, and a rotating intern pool for sorting, mounting and labeling. Second, we present on some micro-photographic techniques for illustrating the species we have collected. We have developed mounting techniques that minimize the 'observer effect' while photographing small wasps, and allow us to work seemlessly between light microscopy and scanning electron microscopy. Additionally, we have some specialized LED illumination domes adapted for use with a compound microscope that help resolve very small specimens. Together, these techniques help us shorten the time lag between specimen acquisition and species description.

Remote microscopy: A success story in Australian and New Zealand plant biosecurity

Michael Thompson
Queensland university of technology, Australia

Rapid and accurate identification of organisms is crucial to many research and applied outcomes. Diagnostics is a critical first step in determining the significance of suspected biosecurity threats posed by emergency plant pests and other invasive pests and pathogens. Remote Microscopy (RM) allows entomologists to interact in real time to identify pests and pathogens, viewing live high quality images via the internet in order to act, particularly in quarantine settings. The Cooperative Research Centre for National Plant Biosecurity's RM network has now expanded to include Thailand, Vietnam, Lao PDR, Malaysia, Indonesia, East Timor, Papua New Guinea, New Zealand and Australia with over 60 locations actively participating in identifications and using RM to educate and train each other. With the release of the new Padil (www.padil.gov.au) has come the Remote Microscope Diagnostics (RMD) portal. This dynamic, adaptable, secure, Padil image and information integrated, freely available service facilitates the "Taxonomic Triage" process, from user to diagnosis and appropriate action. The RMD portal will also include delivery of the microscope feed itself, thus eliminating many of the troublesome IT security issues that have plagued RM users in the past. The RMD portal allows users to upload information, GPS coordinates, images and video for action by a "Triage Officer" who will either identify the pest or utilize the extensive pool of taxonomic expertise found throughout the RM network and greater entomological community in Australia, New Zealand and South East Asia. The RMD portal will also allow the formation of "Triage Organisations" for application to specific lab groups or quarantine bodies, which will allow user group driven application and extensive domestic and international application. The dynamic design of the RMD portal and the extensive pool of expertise available will greatly enhance the diagnostic capacity of regional entomological communities in the form of identifications and the taxonomic triage process as well as in the realms of taxonomic training and the delivery of online training packages.

Making scents of it all: Volatile pheromones of the Cerambycidae

Ann Marie Ray[1], Ian Swift`[2], Lawrence M. Hanks[3], Jocelyn G. Millar[4]

[1]Xavier University, U.S.A., [2]California State Collection of Arthropods, U.S.A., [3]University of Illinois at Urbana-Champaign, U.S.A., [4]University of California, Riverside, U.S.A.

Until recently, little was known of the chemical ecology of longhorned beetles, especially of the role of volatile pheromones in mate location. The last eight years have seen a dramatic increase in the number of volatile pheromones that have been identified for cerambycid species. These pheromones include several compounds that are general attractants for multiple species in multiple subfamilies. Here, we summarize the current knowledge of volatile pheromones of longhorned beetles, including information on the role of pheromones in mating systems, the diversity of pheromone structures, and possible synergistic effects of host plant volatiles with pheromones as a method of attracting longhorned beetles to traps.

Observational notes on the endophallus of Cerambycidae: Comparing everted and non-everted conditions

Junsuke Yamasako[1], Nobuo Obayashi[2]
[1]Ehime University, Japan, [2]Kanagawa Pref., Japan

As recently noticed in Cerambycidae, the structure of the endophallus of male genitalia is valuable not only for distinguishing among species, but also for phylogenetic considerations. Rubenyan (2002) introduced a technique to evert and inflate the endophallus of Cerambycidae by using fine pin and needle. It is the most valuable way for observation of the character of endophallus, but this technique is occasionally limited by the size or condition of the specimen. Furthermore, it is sometimes difficult to evert because the endophallus of Cerambycidae is sometimes very long and consists of complicated structures with large sclerites inside. Contrary to this, the method to observe the endophallus in the inflated condition without eversion is much easier, and may have a universal application for cerambycid beetles. We have adopted this way on our study of Asian Mesosini since 2007 (Yamasako & Ohbayashi 2007), and recently proposed a new observation technique (Yamasako & Ohbayashi 2011, in press). However, the structures of the endophallus in everted and non-everted states have never been compared each other. We describe the techniques and our observations on the character states in both everted and non-everted conditions.

Cerambycidae of Bolivia (Coleoptera: Cerambycidae)

Steven Wayne Lingafelter[1], James E. Wappes[2]
[1]USDA - ARS, U.S.A., [2]San Antonio, Texas, U.S.A.

An overview of the incredible diversity of the Cerambycidae of Bolivia is presented. This project is a joint effort between the Museo de Historia Natural "Noel Kempff Mercado" (MNKM), Santa Cruz de la Sierra, Bolivia, the Florida State Collection of Arthropods (FSCA), Gainesville, Florida, the American Coleoptera Museum (ACMT), San Antonio, Texas, and the Smithsonian Institution, Washington, DC. The project's primary objective is to conduct a survey of the Cerambycidae of Bolivia. Bolivia's large size (424,000 sq. mi.) and its geographically diverse and often mountainous terrain contributes to the challenge. There are numerous remote and virtually inaccessible areas whose cerambycid faunas remain completely unknown. Since the inception of this project, most of the collecting by participants has been in Santa Cruz Department with brief forays into Beni, Cochabamba, La Paz, and recently Tarija. As a result, although our knowledge has increased tremendously, much remains to be done.

Systematics, Phylogeny and Zoogeography

Preliminary findings into the morphology and systematics of Onciderini (Cerambycidae: Lamiinae)

Eugenio H. Nearns[1], Kelly B. Miller[2]

[1]University of New Mexico, U.S.A., [2]University of New Mexico, U.S.A.

Preliminary findings from the first morphological study and cladistic analysis of the tribe Onciderini Thomson (Cerambycidae: Lamiinae) are presented. Onciderini are Nearctic and Neotropical in distribution and get their common name (the "twig girdlers") from the fact that adult females of several genera (e.g., Ecthoea, Lochmaeocles, Oncideres, Psyllotoxus) girdle branches of various host trees. Members of this tribe are known to attack more than 50 different woody plant families, including many economically and agriculturally important species such as avocado, cocoa, and coffee. The main objective of the study is to test the monophyly of the tribe, as well as relationships among the 79 genera and more than 450 species. Of particular interest is elucidating the origin of girdling behavior, as well as the potential discovery of morphological characters associated with girdling. Data presented are based on morphological dissections and illustrations of male specimens representing 20 genera. Morphological characters examined are from the head capsule, mandible, maxilla, labium, pronotum, mesonotum, prosternum, hind wings, and tegmen.

Cerambycidae of North Vietnam

Eduard Vives[1], Steven Lingafelter[2], Pham Hong Thai[3]

[1]Museu Zoologia de Barcelona, Spain, [2]Systematic Entomology Lab Washington, DC, U.S.A., [3]Institute of Ecology and Biological Resources Vietnam Academy of Science and Technology, Vietnam

We present the results of an entomological expedition focussing on Cerambycidae (Coleoptera) to the provinces of Cao Bang, Thai Nguyen and Vinh Phuc in northern Vietnam, undertaken in 2011. Institutional collaborators include the United States Department of Agriculture and Smithsonian Institution, Washington DC, and the Vietnam Academy of Science and Technology's, Institute of Ecology and Biological Resource. More than 400 species of Cerambycidae were collected, of which 323 have been determined to species. One new genus and eight new species were recorded. Results are discussed, along with taxonomic and biogeographically comments on the species studied.

The longhorned beetles of the Itatiaia National Park, Rio de Janeiro State, Brazil

Marcela Laura Monne[1], Miguel Angel Monne[2]

[1]Museu Nacional, Universidade Federal do Rio de Janeiro, Brazil, [2]Museu Nacional, Universidade Federal do Rio de Janeiro, Brazil

The Atlantic Rainforest stretches for about 4,000 km along the Atlantic coast of Brazil from the state of Rio Grande do Norte down to Rio Grande do Sul. It is after the Amazon and the Cerrado the third largest biome in Brazil and, according to Conservation International, it is among the top 5 biodiversity hotspots on Earth. However, at present only approximately 7,3% (94,000) of the original 1,290,692 sq. kilometers of Mata Atlantica remains in Brazil. The National Park of Itatiaia is one of the most important protected areas of the Atlantic Rainforest and from the point of view of the insects, little is known about species of Coleoptera. A survey of the Cerambycidae species recorded in the National Park of Itatiaia, Rio de Janeiro State, Brazil, is presented. The data were based on literature, field work and in the collection of the Museu Nacional, Universidade Federal do Rio de Janeiro. Five Cerambycidae subfamilies are recorded: Cerambycinae, Lamiinae, Lepturinae, Parandrinae and Prioninae. Six hundred forty-eight species are recorded to the park, representing about 30% of the Atlantic Rainforest species, sixty three new distribution records are registered.

Cerambycidae of Brazilian tropical savanna: Diversity and endemism

Marcela Laura Monne Freire[1], Vanessa Souza Machado[2], Juan Pablo Botero[3]

[1]Museu Nacional, Universidade Federal do Rio de Janeiro, Brazil, [2]Museu Nacional, Universidade Federal do Rio de Janeiro, Brazil, [3]Museu Nacional, Universidade Federal do Rio de Janeiro, Brazil

The Cerrado biome is the regional name given to the Brazilian tropical savanna and is located on the large plateau that occupies the central highlands. Influenced by the 4 surrounding biomes: Atlantic Rainforest, Caatinga, Amazon and Pantanal. The fauna and flora of the Cerrado is extremely rich but little is known about insects and there is no survey concerning the Cerambycidae fauna of the Cerrado. The preliminary results shows seven hundred species distributed in five subfamilies, Cerambycinae, Lamiinae, Prioninae, Lepturinae and Parandrinae. The most diverse is Cerambycinae with 455 species of which 128 are endemic, 51 occurs also in Amazon Rainforest, 164 in common with Atlantic Rainforest and 60 are large distributed in Neotropical region.

Systematics, Phylogeny and Zoogeography

Phylogeny of the invasive *Agrilus planipennis* Fairmaire (emerald ash borer - EAB) and its relatives (Coleoptera: Buprestidae)

Maria Lourdes Chamorro[1], Eduard Jendek[2]

[1]*Systematic Entomology Laboratory, U.S.A.,* [2]*Ottawa Plant Laboratory, Canada*

Agrilus planipennis Fairmaire (emerald ash borer - EAB) is a highly destructive invasive wood-boring insect pest from Asia that kills healthy, non-Asian ash (Fraxinus) trees. It has invaded areas of eastern North America (U.S.A. and Canada) and Moscow, altering native landscapes and costing hundreds of millions of dollars for control and eradication. Understanding its phylogeny will allows scientists to make predictions about potential new invasive species with similar evolutionary histories and adaptations and help determine ways to manage them. A preliminary morphology-based phylogenetic analysis was undertaken to infer the sister-group relationships of Agrilus planipennis. One hundred fourteen characters were coded for 40 taxa and analyzed under parsimony. Results indicate an affinity with species in the A. cyaneoniger group and groups of species with distributions in Southeast Asia. Taxon sampling, homoplasy, and the value of larval characters is discussed.

Diversity of the buprestid beetles of the Korean peninsula (Coleoptera: Buprestidae)

Jun-Gu Lee
Chungnam National University, Republic of Korea

This presentation provides an overview of the diversity of the buprestid beetles of the Korean peninsula. In spite of the economic importance of Buprestidae in forest and agriculture, the species diversity of these beetles in the Korean peninsula has not been well studied. In fact, no single comprehensive study has been presented on the diversity of Korean buprestids. Therefore, this presentation will provide the first review of the Korean buprestid beetles, based mainly on the results of morphological taxonomic studies. A total of 120 species in 22 genera of Buprestidae have been found in the Korean fauna; eight of these are recognized as endemic to South Korea, including six previously undescribed species. This presentation also provides the results of comparison of the species and generic diversity of Korean buprestid beetles with that of buprestid beetles in other East Asian countries.

Pseudocryptic speciation of *Chrysochroa fulgidissima* (Coleoptera: Buprestidae) with two new species from Korea, China and Vietnam

Taeman HAN[1], TaeHwa KANG[2], Jongchel JEONG[3], Young Bo LEE[4], Hyo Jung CHUNG[5], Sangwook PARK[6], Seungwhan LEE[7], Ki Gyoung KIM[8], Hae-Chul Park[9]

[1]National Academy of Agricultural Science, Republic of Korea, [2]National Academy of Agricultural Science, Republic of Korea, [3]Seodaemun Museum of Natural History, Seoul, Republic of Korea, [4]National Academy of Agricultural Science, Suwon, Republic of Korea, [5]Kyungpook National University, Daegu, Republic of Korea, [6]Seoul National University, Seoul, Republic of Korea, [7]Seoul National University, Seoul, Republic of Korea, [8]National Institute of Biological Resources, Incheon, Republic of Korea, [9]National Academy of Agricultural Science, Republic of Korea

The jewel beetle Chrysochroa fulgidissima was taxonomically reassessed based on molecular analyses of COI ans 16S rRNA gne partial sequences, and morphological approaches, excluding the subspecies Chrysochroa fulgidissima adachii. Molecular (three data sets, COI 16S, COI+16S in mt DNA) and morphological (quantitative and qualitative characters) evidence suggested that Ch. fulgidissima consists of four independent species found in seven geographical regions, namely Korea, Japan and Taiwan, China (GuangXi and Hainan) and Vietnam, and Okinawa Island. As a result of the large genetic divergences and subtle morphological differences amongst these populations, we were able to infer that the nomonotypical subspecies, Chrysochroa fulgidissima fulgidissima, is divided into three pseudocryptic species that have undergone allopartric speciation events. Thus, we propose that the subspecies Chrysochroa fulgidissima alternans should be upgraded to valid specific status. We also provide a description of two new species, Chrysochroa coreana sp. nov. from Korea, and Chrysochroa pseudofulgidissima sp. nov. from China and Vietnam.

Marine Entomology - Then and Now

Lanna CHENG
University of California, San Diego, U.S.A.

Insects are generally thought to be absent from the sea which covers some 70% of the earth's surface. Why insects failed to conquer the largest surface area on earth has been a subject of debate for at least 100 years. In fact, insects are not only found in various marine habitats but also live in the open ocean, thousands of kilometers away from land. Why marine insects remained largely unknown was probably because few entomologists go to sea and most marine biologists are not aware of them. According to the World Register of Marine Species (WoRMS) at least two thousand insect species belonging to some 20 orders have been described. Most are members of Coleoptera, Diptera or Heteroptera. They can be found in salt marshes, mangrove swamps, rock pools, tidal ponds, beaches, bays, lagoons and the open ocean. Although adults of many species may be found on land, their larvae are often associated with algae or other marine plants that remain submerged underwater either entirely or partially during tidal rise and fall. Their life cycles are thus closely dependent or governed by tidal or lunar rhythms. The earliest paper on a marine stapylinid was published in 1783. Literature on various species appeared sporadically during the next 200 years and was widely scattered. No attempt was made to gather all the information together until 1976 when 'Marine Insects' was published (Available for free download at: escholarship.org/uc/item/1pm1485b). Research on marine insects has blossomed since then. Marine Entomology has finally come of age?

Distribution of the ocean-skater *Halobates sericeus* and paleo-oceanography

Sarah Sin Tong Leo[1], Lanna Cheng[2], Felix Sperling[3]
[1]*University of Alberta, Canada,* [2]*University of Alberta, Canada,* [3]*University of Alberta, Canada*

The oceanic water strider (or ocean-skater) Halobates sericeus Eschscholtz has disjunct distributions in the Pacific Ocean with a northern and a southern population widely separated by an equatorial zone. It is sensitive to sea surface conditions. Consequently, its distribution and population structure can provide insight into environmental changes on the ocean surface on both recent and historical scales. We assessed the genetic diversity and population structure of H. sericeus in the Pacific Ocean using one mitochondrial (COI) and two nuclear (EF1α, ITS-1) gene markers. These genetic markers indicated that the northern and southern populations are evolutionarily distinct with limited gene flow, and that these populations separated 20 to 50 thousand years ago. This implies that physical conditions or biotic interactions on the surface of the Pacific Ocean have provided significant barriers to gene flow since the late Pleistocene or earlier, creating biotic stability over large geographical and temporal scales in spite of a long history of global climate change.

Temperature tolerance of oceanic sea skaters, *Halobates* (Heteroptera: Gerridae), and ocean dynamics

Tetsuo Harada[1], Shiho Takenaka[2], Takero SEKIMOTO[3], Yuki OSUMI[4], Takao INOUE[5], Mitsuru Nakajyo[6], Chihiro KATAGIRI[7]
[1]Kochi University, Japan, [2]Kochi University, Japan, [3]Kochi University, Japan, [4]Kochi University, Japan, [5]Kochi University, Japan, [6]Kochi University, Japan, [7]Hokkaido University, Japan

This study was performed to clarify how weather and ocean dynamics affect resistance to temperature change in the oceanic sea skaters, Halobates. Heat coma temperature (HCT) was measured mainly for the adultsof threeHalobates species collected from a fixed sampling location (12°N, 135°E) and other locations (0ºN-8N, 12ºN-17ºN,130ºE-140ºE) in the Western tropical Pacific Ocean,and also from 13locationsin the eastern area of the India Ocean (08°N- 6°S, 86º'E-76ºE). Halobatessericeus(distributed in the wide latitude zone of 5ºN-40ºN)has shown higher HCT (35.6 ºCon average) than H. germanus (distributed zone of 0ºN-35ºN)(32.9 ºC)and H. micans (distributed mainly around the equator) (31.6ºC) (P=0.035) in a sampling area of the Western Pacific Ocean. The average HCT of individuals collected from the Pacific Ocean was significantly higher during the first half (10 days) of the sampling period at the fixed sampling point than during the second half, at 35.0ºC and 34.0ºC, respectively. The reduction in heat tolerance during the second half may have been caused by a decrease in air temperature due to rain fall that occurred around the sampling point during the arrival of Typhoon No. 6. Adultsof H. micans and H. germanuscollected from the area within 75ºE-95ºE, 5ºS-10ºS of the Indian Ocean, showed extremely high HCTs of 37º-40ºC on average.The exceptionally strong heat tolerance may be related to the fact that this area shows the largest intra-seasonal air temperature variation among all oceans on the globe.

Ecology of three endangered sea skaters (Heteroptera: Gerridae) in Japan

Terumi Ikawa[1], Yuichi Nozoe[2], Sugihiko Hoshizaki[3], Hidehiko Okabe[4]

[1]Morioka University, Japan, [2]Kujukushima Visitor Center, Japan, [3]The University of Tokyo, Japan, [4]National Institute of Advanced Industrial Science and Technology, Japan

Halobates matsumurai, H. japonicus and Asclepios shiranui are the only coastal sea skaters known in Japan. For the past several decades they have become rare in most localities and have now been designated as endangered. Their present distribution ranges are more limited compared to those in the 1950's or earlier. They are found in quiet waters along jagged coastlines without overdevelopment or pollution. Among the three, the habitat of A. shiranui is most restricted, known only in the coasts of Tsushima Island and northwestern Kyushu Is. H. matsumurai is found along the coasts of Tsushima Is., northwestern Kyushu Is. and southwestern Honshu Is. On the other hand, the records of H. japonicus show it scattered over wide ranges, extending more than 1500 km from the southwestern coast of Honshu Is. to the Nansei Islands. A. shiranui and H. matsumurai often co-occur in small coves or inner bays but H. japonicus has never yet been found to co-occur with either A. shiranui or H. matsumurai. Year-round studies on life cycles were carried out on H. matsumurai and A. shiranui in the northwestern coast of Kyushu Is. Both appeared to have more than one generation a year and to overwinter in the egg stage. Eggs of H. matsumurai were laid on natural sandstones and man-made sandstone walls along the shore, mostly above the average sea level. The eggs had very hard shells, presumably adaptive to protect them from desiccation, solar radiation and wave action, especially during the overwintering period.

Ecology, distribution and molecular phylogeny of the marine midge *Pontomyia* (Diptera: Chironomidae)

Danwei Huang[1], Lanna Cheng[2]
[1]*University of California, San Diego, U.S.A.*, [2]*University of California, San Diego, U.S.A.*

Pontomyia (Diptera: Chironomidae) is a genus of exclusively marine and flightless midges with one of the shortest known adult life spans (< 3 hours). Larval stages are spent entirely underwater among submerged vegetation or algal turf. Males have modified wings to propel them over water while females are wingless, almost completely legless and depend on the males to find and mate with them on the sea surface. Males die shortly after mating and females die after laying eggs which are encased in a gelatinous coil. Four species have been described: P. natans, P. cottoni, P. oceana, and P. pacifica. Pontomyia cottoni is endemic to Australia while the remaining three species are widely distributed along island shores in the Indo-Pacific. One species from the Atlantic remain to be described since no adult males have yet to be collected. Results from a four-gene phylogenetic reconstruction showed that P. natans, P. oceana and P. pacifica are each well-supported clades, with P. natans as sister to P. oceana + P. pacifica. The commonest and most widespread species, P. natans has been collected from Samoa, Japan, Fiji, Malaysia, Marshall Islands, Queensland Australia, and Taiwan in the Pacific, and Maldives and Christmas Island in the Indian Ocean, locations that are thousands of kilometers apart. Males from different locations are morphologically indistinguishable, but genetic distances based on mitochondrial COI are extraordinarily large within this species (up to 15%), indicating possible cryptic speciation. Mechanisms for cryptic speciation in these unique marine midges remain to be discovered

Live with the rhythm of the tides: Evolution of local adaptations in adult emergence time of the marine midge *Clunio marinus* (Diptera: Chironomidae)

Tobias S. Kaiser
Max F Perutz Laboratories, Austria

Marine midges of the genus Clunio HALIDAY 1855 are found on many coasts worldwide. All species of the genus that were studied in detail display diurnal and lunar rhythms of adult emergence, which enable them to synchronize reproduction to the most suitable tides. As the pattern, amplitude and timing of the tides differs along the coast, Clunio species with different geographic distribution as well as different populations of wide-spread Clunio species require specific timing adaptations to the local tides. Phylogenetic analysis of the European species of the genus Clunio revealed that there is both convergent and divergent evolution. Genetically closely related species, such as Clunio marinus and Clunio balticus, have divergent timing adaptations due to the different ecological requirements of their habitat. In turn, genetically divergent species, such as Clunio mediterraneus and Clunio ponticus, have similar timing phenotypes due to identical ecological niches. The species Clunio marinus, being distributed along the European Atlantic Coast from Spain to Iceland, comprises a variety of locally adapted timing races. A population genetic survey revealed that likely all of these timing races are derived from the same ancestor and evolved within less than 20,000 years, underpinning the enormous evolutionary flexibility of Clunio's timing traits. Crossing experiments with Clunio marinus identified some of the genomic loci that control the timing traits and showed that lunar and diurnal timing are genetically not independent. The ongoing Clunio marinus genome project will soon enable the study of these timing traits and their evolution at a new level.

A marine insect that counts - Mechanism of Circa-semilunar emergence rhythm of *Pontomyia oceana* (Diptera: Chironomidae)

Keryea Soong[1], In-How Chang[2]
[1]*National Sun Yat-sen University, Taiwan,* [2]*National Sun Yat-sen University, Taiwan*

Lunar and semilunar cycles of biological activities are common in marine and even some terrestrial organisms (Endres & Schad, 2002; Naylor, 2010), of which some are actually controlled by endogenous oscillations that are in turn entrained by environmental cues (Hauenschild, 1960; Neumann, 1966; Saigusa, 1980; Reid & Naylor, 1985; Luning et al., 2008). How the periods (e.g., ~15 or ~30 d) of such internal rhythms are maintained in the absence of external entraining factors has been a challenging question (Neumann & Heimbach, 1985). This paper reports a case supporting the frequency demultiplication hypothesis, in which the internal circasemilunar emergence rhythm of an intertidal midge, Pontomyia oceana, is based on counting the cycles of endogenous circadian rhythms.

Systematics, Phylogeny and Zoogeography

Zoogeography of coastal marine Staphylinidae (Coleoptera)

J. Howard Frank[1], Kee-Jeong Ahn[2]

[1]*University of Florida, U.S.A.,* [2]*Chungnam National University, Daejeon, Republic of Korea*

Staphylinidae (Coleoptera) are currently the insect family with the most described species, over 55,000, and yet perhaps as many as 80% of the world's staphylinid species are undescribed. Fewer than 400 staphylinid species have yet been determined to be obligate inhabitants of seashores of the world. Evolution of specialization to coastal habits is polyphyletic among coastal Staphylinidae, occurring in eight subfamilies. Aleocharinae are the most species rich of the eight subfamilies with coastal representatives. The Pacific Ocean has many more species of coastal staphylinids than do the other oceans. The United States has more species of coastal staphylinids than do eight other countries. Some species (Group A) belong to genera having mainly non-coastal species, whereas some (Group B) belong to genera in which all species are coastal. In Group B, 40 genera occur only on the shores of the Pacific Ocean, and 10 genera only on the shores of the world's other oceans, suggesting that the Pacific Ocean is the main cradle of evolution of specialist coastal Staphylinidae. In Group A, about as many species are known from the other oceans as from the Pacific as might be expected when evolution at the species level is more recent than at the generic level. It is appropriate that this symposium is held in South Korea, a Pacific-rim country rich in coastal Staphylinidae.

Phylogeny of the marine littoral genus *Cafius* (Coleoptera: Staphylinidae)

Mi-Jeong Jeon[1], Kee-Jeong Ahn[2]
[1]*National Institute of Biological Resources, Republic of Korea,* [2]*Chungnam National Universtiy, Republic of Korea*

A phylogenetic analysis of the marine littoral genus Cafius Stephens is presented based on molecular characters. The data set comprised partial mitochondrial COI (910 bp), COII (369 bp), 12S rDNA (351-354 bp), 16S rDNA (505-509 bp) and nearly complete sequences of 18S rDNA (1814-1830 bp) for 37 species. Twenty-seven Cafius species, representing five of six subgenera, two Remus Holme species, three Phucobius Sharp species, monotypic Thinocafius Steel and four outgroups were included. The sequences were analysed simultaneously by parsimony analysis in Tree Analysis Using New Technology (TNT) with traditional manual alignment, direct optimization (DO) in the program POY4 under a variety of gap costs and partitioned Bayesian analysis for the combined data. The genus Cafius and nearly all of its subgenera were not supported as being monophyletic. Instead, all analyses (parsimony trees, DO tree under equal weighting and Bayesian tree) showed monophyly of Cafius + Phucobius + Remus + Thinocafius (clade Z) and all seven nested clades (A-G). However, the phylogenetic relationships among clades A?G differed among the analyses. The genus Phucobius was recovered as a monophyletic group within Cafius. The genus Remus was not monophyletic but formed a clade with C. rufescens Sharp and C. rufifrons Bierig within Cafius. The genus Thinocafius formed a clade with C. caviceps Broun, C. litoreus (Broun) and C. quadriimpressus (White) within Cafius. We propose new concepts for the genus Cafius and its related genera, and the seven nested clades.

Molecular phylogeny and coastal habitat evolution of the genus *Aleochara* (Coleoptera: Staphylinidae)

Jeong-Hun Song[1], Kee-Jeong Ahn[2]

[1]Chungnam National Universtiy, Republic of Korea, [2]Chungnam National Universtiy, Republic of Korea

A revised molecular phylogeny of the genus Aleochara Gravenhorst is presented. The data set comprised partial mitochondrial COI (1373 bp), COII (577 bp), and complete sequences of tRNA leucine (71 bp) between them, for 56 Aleochara and eight outgroups. We added eight coastal species with 15 populations (Aleochara fucicola Sharp, A. littoralis (Maklin), A. nubis Assing, A. puetzi Assing, A. squalithorax Sharp, A. sulcicollis Mannerheim, A. trisulcata Weise, and A. zerchei Assing), which were not included in the previous analysis. The sequence data were analyzed by Maximum Likelihood, Bayesian and parsimony methods. The monophyly of the genus Aleochara, curtula clade, bilineata clade and clades A to D containing the coastal species were strongly supported by all of three analyses. Based on the phylogenies, we hypothesize that multiple origins of seashore habitat have occurred throughout the genus Aleochara.

Histeridae, Salpingidae and Hydrophilidae (Coleoptera) on seashore of Japan

Masahiro Ohara[1], Norio Kobayashi[2]
[1]Hokkaido University, Japan, [2]Saitama Prefectural University, Japan

Japanese coastline is the sixth longest in the world being about 29,751 km. Japan is also a very long country from north to south, the northernmost point is at 45˚33' N and the southernmost is at 20˚25'N, its distance is same from Milano, Europe to Sahara Desert, in Africa. Animal living on the Japanese seashore vary enomously and show the Palaearctic to Oriental zoogeograpical elements. Fauna of the littoral beetles is also very rich, especially the families Staphylinidae, Hydrophilidae, Histeridae, Agyrtidae, Scarabaeidae, Elateridae, Tenebrionidae, Salpingidae and Curculionidae. Topics for this presentation as follows: (1) On the general information of the Japanese littoral beetles. (2) On the species of the genera Hypocaccus, Eopachylopus and Hypocacculus (Histeridae) and their distributions. (3) On the species of the genus Aegialites (Salpingidae) and their distributions. (4) On the species of the genus Cercyon (Hydrophilidea) and their distributions, habitat and phylogeny. Additionally, the damage of the coastline and animal living on seashore by Tsunami, 11th March 2011, in Tohoku area, Japan is reported.

Concluding remarks

Kee-Jeong Ahn
Chungnam National Universtiy, Republic of Korea

This symposium on marine insects is coming to an end and I would like to thank very much the speakers and organizers for giving me the floor to be the last speaker and to make the closing remarks. It is a special honor for me and I really appreciate it. I consider this half-day meeting as a highly productive and informative gathering because of the excellent scientific quality of all the presentations. Taxonomically, our symposium could be divided into three parts, three on Gerridae (Heteroptera), three on Chironomidae (Diptera) and four on Coleoptera. It may be useful to point out that this is the third symposium on marine insects during an ICE. The first occurred in Washington D.C. in 1976 and the next was held in Florence, Italy in 1996. I will be trying to give some personal views on what seemed to me the most important. As a taxonomist of the beetle family Staphylinidae, I can say that I learned a lot about marine insects. I hope that you learned a lot as well. I wish that this symposium will serve as a stepping-stone toward future research programs and networks on marine insects.

Elucidating Lepidoptera evolution: A tale of two approaches

Niels Peder Kristensen
Natural History Museum of Denmark, Denmark

The grand picture of lepidopteran evolution has long been drawn exclusively on the basis of morphological findings. It showed a tentatively resolved initial sequence of origins of non-ditrysian lineages followed by a radiation at the basis of the Ditrysia, which is only very partially resolved. The molecular approach to Lepidoptera systematizing, with analyses of sizable gene and taxon sets, have led to considerable progress in refining family-/superfamily-level classification, but few relationships above superfamily level are yet robustly supported. Expectedly forthcoming massive novel genomic data may enable significantly better resolution of this ditrysian 'backbone', but if many ditrysian superfamilies indeed originated within short time spans, a number of internodes in the tree may remain retrievable with difficulty, if at all. The role of the morphological approach to evolutionary research on Lepidoptera will change. Morphological characters will continue to assist in choosing between alternative solutions emerging from molecular analyses, and/or may highlight need for additional investigation in cases where results from molecular analyses appear conclusive when viewed in isolation. But the role of morphological findings will increasingly be providing data, which, when mapped on molecule-generated cladograms, add to the interest of the latter. Glossatan Lepidoptera may seem to be overall structurally homogeneous, but much structural modifications actually did take place during their evolution. Several long-standing questions about "where?", "how many times independently?", and "in how many recognizable steps?" notable structural innovations evolved still remain unanswered.

From soil to tree: the ground plan of the lepidopteran larval trunk, and notable early deviations

Steen Thorleif Dupont
Natural History Museum of Denmark, Denmark

The 'typical' neolepidopteran caterpillar represents the larval type of more than 99% of the Lepidoptera. The 'typical caterpillar' with crotchet bearing abdominal prolegs has however evolved from a very different soil dwelling larvae type without prolegs. The study of larvae of the non-Neolepidoptera including Micropterix, Agathiphaga, Heterobathmia, Eriocrania and Acanthopteroctetes is used to discuss the evolution and morphology of the 'typical caterpillar'. The Micropterix and Agathiphaga have larval with trunk a trunk morphology too derived to discuss the characteristics of the larval ground plan, they have important life histories that reflect a succession form a soil dwelling organism to that of a more arboreal free living organism as seen in the neolepidopterans. The leaf mining life style and the larval morphology of Eriocrania and Acanthopteroctetes and especially Heterobathmia appear to be informative with regards to the lepidopteran larval ground plan and the trunk morphology of the 'typical caterpillars'. The trunk morphology of the three non-neolepidopterans is therefore presented in order to discuss three key points; 1) the Evolution of the autapomorphic apodemeless trunk musculature, 2) the secondary locomotory structures (calli) of the leaf mining larvae and 3) the calli as possible structural predecessor to the abdominal proleg

More genes, more taxa, more questions? Inching towards a molecular phylogeny of Lepidoptera

Andreas Zwick[1], The Leptree Consortium (www.leptree.net)[2]

[1]*State Museum of Natural History Stuttgart, Germany,* [2]*The University of Maryland, U.S.A.*

While detailed morphology-based studies provide well supported hypotheses for early splits into several (now) relatively species-poor families, relationships between families and superfamilies of the Ditrysia, which comprise 98% of the approximately 157,000 named lepidopteran species, are still rather poorly understood. Recent progress in molecular phylogenetics of Lepidoptera resulted in numerous new hypotheses, several of which are reflected in a publication (van Nieukerken et al. 2011: Zootaxa 3148) that provides a revised higher classification of the order. This presentation outlines the changes and compares the evidence in support of these changes with unpublished results from a much larger molecular study, the 'Assembling the Tree of Life Lepidoptera' project (http://www.leptree.net). These new results are based on up to 19 nuclear, protein-coding genes (18.9kbp) for 847 species that represent almost all lepidopteran families and subfamilies. The broad taxon and gene sampling provides numerous well supported phylogenetic hypotheses within families and superfamilies, many of which recover or complement existing hypotheses. In contrast, the 'backbone phylogeny' of Ditrysia, i.e., relationships between superfamilies, has exceedingly short branches and remains only partly resolved.

On the phylogenetic affinities of some enigmatic Lepidoptera

Marko Mutanen[1], Maria Heikkila[2], Lauri Kaila[3]

[1]University of Oulu, Finland, [2]University of Helsinki, Finland, [3]University of Helsinki, Finland

The phylogeny of the order Lepidoptera has recently been under several molecular investigations. While the monophyly of many lepidopteran superfamilies and lower ranks seems well-established, the deepest nodes remain frequently ambiguous. Similarly, the phylogenetic affinities of several rare and/or enigmatic taxa remain to be scrutinized. We have added several taxa of particular interest to the previously published 350 species dataset that comprehensively represents the lepidopteran diversity. The added taxa include Siloscinae, Tanaoctena, Copromorpha, Callizygaena, Meharia (2 spp.), Prodidactis and an unknown, recently discovered and unnamed taxon not associated with any superfamily. We were able to associate, at least roughly, these taxa with other lepidopteran taxa, some with high, others with lower confidence. Even so, the interrelationships of deeper nodes remain uncertain and require further attention.

Getting a sense of time for massive radiations in Lepidoptera

Niklas Wahlberg
University of Turku, Finland

The diversity of life on Earth is enormous and our task of documenting it is still underway. One important part of this documentation is understanding the generation and maintenance of biodiversity over evolutionary time frames. When have major divergences happened? How have these divergences happened? I will be investigating these questions using the megadiverse clade of Lepidoptera (butterflies and moths) as my model group. In this talk, I will review what we know about the evolutionary history of Lepidoptera and point to the directions we are going in the future to understand why there are at least 150,000 extant species in all the world's habitats.

Progress toward fossil and molecular dating for the Lepidoptera Tree of Life

Jae-Cheon Sohn[1], Donald Davis[2], Charles Mitter[3], Jerome Regier[4], Michael Cummings[5]

[1]University of Maryland, U.S.A., [2]National Museum of Natural History, Smithsonian Institution, U.S.A., [3]University of Maryland, U.S.A., [4]University of Maryland, U.S.A., [5]University of Maryland, U.S.A.

Recent remarkable progresses in molecular clock methods make it feasible to estimate divergence times for phylogenetic branch points, and such estimates have become routine in evolutionary studies. However, reliable molecular dating is strongly dependent on having multiple fossils that are securely identified and of sufficient age. The availability of such fossils is strongly taxon-dependent. Among the five largest insect orders, only the Lepidoptera have a fossil record less rich than what its modern diversity would suggest (Labandeira & Sepkoski, 2003). This depauperate record and the paucity of explicitly synapomorphy-based identifications of lepidopteran fossils have hindered rigorous tests of evolutionary hypotheses for Lepidoptera. Several empirical studies have highlighted the critical effects of the number and temporal distribution of fossil calibrations, interpretation of the relationships between fossil and extant taxa, and how fossil constraints are treated in molecular dating analyses. The Lepidoptera Tree of Life Consortium has completed a catalog of all known lepidopteran fossils, and is completing an estimate of phylogeny across the Lepidoptera based on 19 nuclear genes. Together these tools will make it possible to explore how fossil calibrations affect divergence time estimates for lepidopteran lineages, and hence to develop reliable molecular dating schemes for the Lepidoptera. We provide an updated overview of the lepidopteran fossil record and identify a suite of promising fossil calibrations for molecular dating analyses of Lepidoptera.

Hepialoidea revisited in the light of the discovery of a new higher-level taxon

Thomas Johannes Simonsen[1], Niels Peder Kristensen[2]
[1]*Natural History Musem, London, United Kingdom,* [2]*Natural History Museum of Denmark (Zoology), Denmark*

Hepialoidea comprise only a few hundred species in approximately 60 genera, however, the superfamily is of considerable evolutionary and zoogeographical importance. It comprises the majority of the sister lineage of Heteroneura and, apart from the almost globally distributed Hepialidae s. str. and the Holarctic genus Gazoryctra, the major lineages within the subfamily have limited known distributions restricted to Australia, southern Asia, sub-Saharan Africa and the Neotropics, with each lineage usually being restricted to a limited area within a region. The superfamily thus remains crucial for understanding the early evolution and zoogeography of the whole Lepidoptera. Unfortunately the higher-level relationships of the 12 principal lineages of Hepialoidea are very poorly understood, and studies into the superfamily's evolutionary biology are therefore at the present little more than educated guesses. This lack of understanding is partly due to the scarcity of specimens in collections and partly due to difficulties in establishing which taxon is the sister group of the remaining superfamily. Here we report the discovery of a new, higher-level taxon in Hepialoidea together with re-examination of the adult morphology of key taxa, and discuss the implications for understanding the phylogenetic relationships and classification of the superfamily.

Phylogeny of the lower Heteroneura: A bunch of tiny leafminers, gallers and flower feeders

Erik J. van Nieukerken[1], Donald R. Davis[2], LepTree Consortium[3], Douglas Hilton[4]

[1]Netherlands Centre for Biodiversity Naturalis, Netherlands, [2]National Museum of Natural History, Smithsonian Institution, Washington DC, U.S.A., [3]University of Maryland, MD, USA, U.S.A., [4]Institute of Medical Research, Victoria, Australia

With just over 1.1% of all lepidopteran species, the few monotrysian families constitute a very small portion of the Heteroneura, largely formed by the Ditrysia. However, knowledge of these basal clades is essential to understand how Ditrysia could arise and flourish. Recent molecular studies never support a monophyletic Monotrysia, and the 19 gene analysis (Regier et al., in preparation) reveals four monophyletic clades: Nepticuloidea, Andesianidae plus Adeloidea, the Australian Palaephatidae plus Tischeriidae and the south American Palaephatus as sistergroup to Ditrysia. Monophyly of Australian palaephatids with Tischeriidae is a novel finding. Within Nepticulidae the division in the Australian Pectinivalvinae and the rest is not supported in the 19 gene analysis nor in a 3 gene analysis with more taxa. Rather, Trifurculini are sistergroup to a clade comprising both Pectinivalvinae and Nepticulini. Within Adeloidea, the genus Tridentaforma forms a separate clade, not in the Prodoxidae, and Adelidae are not monophyletic, unless Heliozelidae are incorporated. Although leafmining occurs in many groups, the phylogeny does not rule out the possibility of multiple origins of leafmining from other ways of endophytic feeding. In Heliozelidae we report an undescribed high diversity both in North America and Australia. An initial analysis shows that Vitaceae might be a possible ancestral host family. Australia has probably as many species as are known in the rest of the world, with potentially several new genera and possibly a novel life history involving flower or seed mining. Several known North American species are part of a complex of cryptic species.

Acanthopteroctetidae and their importance for understanding the early evolutionary history of Lepidoptera

Jadranka Rota
University of Copenhagen, Denmark

Based on comparative morphology, Acanthoptertoctetidae are believed to be one of the groups that arose in the earliest evolution of Lepidoptera, successively splitting off after four other lineages: Micropterigidae, Agathiphagidae, Heterobathmiidae, and Eriocraniidae. Hence, this family is the putative sister group to all other Lepidoptera, a clade containing about 99.9% of the order's species richness that includes all but one of the 'tongue-moths' or Glossata (excluding Eriocraniidae, the earliest glossatan lineage). Despite such great species richness, this large clade is morphologically uniform compared with the earliest lineages of Lepidoptera. Studying the morphology of Acanthopteroctetidae in the context of a new multi-locus molecular phylogeny of these ancient lepidopteran lineages will help us determine how the structural features of Acanthopteroctetidae relate to the lepidopeteran and glossatan ground-plans. I will discuss the implications of the new molecular results with special reference to the morphology of the acantopteroctetid adults.

20 million years of evolution in Hawaii's most diverse genus, *Hyposmocoma* (Cosmopteridídae)

Daniel Rubinoff
The University of Hawaii, U.S.A.

Hyposmocoma is an endemic Hawaiian radiation with perhaps 1,000 species, most of which have not been described. The caterpillars all carry silk cases which show spectacular variation across lineages and which are frequently diagnostic. The larvae also vary widely in their ecologies, and while most are scavengers or herbivores, some represent the only case of snail-eating Lepidoptera. Other lineages are amphibious, spending weeks totally submerged or on dry ground, representing unprecedented tolerances for aquatic/terrestrial transitions. The relationships between over 12 of these divergent lineages are strongly supported by multi-gene analyses under both Maximum likelihood and Bayesian models. Results suggest remarkable complexity in the patterns of speciation and generation of evolutionary novelty across Hyposmocoma. Even taxa on the ancient atolls of the Northwest Hawaiian Islands represent a mix of basal-branching and more derived lineages. Further, molecular data suggests that each volcano on each island supports a unique fauna of Hyposmocoma species, arguably the finest-scale example of speciation across the archipelago. These patterns suggest that Hyposmocoma are effective dispersers over long time periods, but not over the relatively short periods needed to prevent localized speciation. The extremely restricted distributions of Hyposmocoma species suggest they would be good models for conservation planning, and that they may have already suffered widespread extinction of species due to anthropogenic perturbations of the islands.

Phylogenetic relationships of Gelechiidae (Lepidoptera)

Sangmi Lee
Arizona State University, U.S.A.

The Gelechiidae (Lepidoptera) are one of the largest families in microlepidoptera with about 4,530 species in 507 genera in four subfamilies in the world (Hodges, 1999). The higher classification of subfamilies and tribes within the Gelechiidae has been controversial. Karsholt and Razowski (1996) recognized three subfamilies and seven tribes in this family: Gelechiinae (Apatetrini, Anomologini, Teleiodini, Gelechiini, Gnorimoschemini, Anacampsini, and Chelariini), Pexicopiinae, and Dichomeridinae. Hodges (1999) recognized four subfamilies (Physoptilinae, Gelechiinae, Pexicopiinae, and Dichomeridinae) without considering tribes. Recently, Ponomarenko (2006) used male genital musculature and traditional morphological characters to propose five subfamilies and twelve tribes: Physoptilinae, Anomologinae (Anomologini, Apatetrini, Aristoteliini, Pexicopiini), Gelechiinae (Gnorimoschemini, Gelechiini, Litini), Anacampsinae (Anacampsini, Brachmiini), and Dichomeridinae (Dichomeridini, Chelariini, Anarsiini). This study provides the phylogenetic relationships of higher taxa in family Gelechiidae. Additionally phylogenetic relationships of Holarctic Litini (formerly Teleiodini) are postulated with the analysis of evolution of host plant preferences and biogeography.

Phylogenetic relationships of Tortricidae - the scene from root to fruit

Richard L. Brown[1], Joaquin Baixeras[2], Sangmi Lee[3]
[1]*Mississippi Entomological Museum, U.S.A.,* [2]*University of Valencia, Spain,* [3]*Arizona State University, U.S.A.*

A recent molecular phylogeny of Tortricidae is reviewed and compared with historical hypotheses regarding phylogenetic relationships based on various morphological characters. The molecular phylogeny supports Bactrini + Endothenini + Olethreutini as the sister group to Enarmoniini + Eucosmini + Grapholitini, whereas the Horak-Brown hypothesis based on morphology proposed a paraphyletic relationship of Olethreutini to the latter tribes. The Horak-Brown hypothesis that Eucosmini is paraphyletic relative to Grapholitini was not supported by the molecular phylogeny, but the latter may have been biased by the low number and choice of genera sampled. Phylogenetic relationships of the tribes of Olethreutinae are reanalyzed by using novel morphological characters of de-scaled moths, e.g., the endoskeleton, appendages, and patterns of scale sockets, combined with traditional characters of wing venation and shape, male sex scales, forewing pattern, and male and female genitalia.

Non-synonymous changes and increased gene sampling improves phylogenetic estimates for higher-level groups within leaf-mining moths and relatives (Lepidoptera: Gracillariidae)

Akito Yuji Kawahara[1], Issei Ohshima[2], Atsushi Kawakita[3], Jerome Regier[4], Charles Mitter[5], Michael Cummings[6], Donald Davis[7], David Wagner[8], Jurate De Prins[9], Carlos Lopez-Vaamonde[10]

[1]University of Florida, U.S.A., [2]Kyoto Prefectural University, Japan, [3]Kyoto University, Japan, [4]University of Maryland, U.S.A., [5]University of Maryland, U.S.A., [6]University of Maryland, U.S.A., [7]Smithsonian Institution, U.S.A., [8]University of Connecticut, U.S.A., [9]Royal Museum of Central Africa, Belgium, [10]INRA, France

Researchers conducting molecular phylogenetic studies are frequently faced with the decision of what to do when weak branch support is obtained for key nodes of importance. As one solution, the researcher may choose to sequence additional orthologous genes of appropriate evolutionary rate for the taxa in the study. However, generating large, complete data matrices can become increasingly difficult as the number of characters increases. A few empirical studies have shown that augmenting genes even for a subset of taxa can improve branch support. We target Gracillariidae, a Cretaceous-age (~100 Ma) group of leaf-mining moths to test whether the strategy of adding genes for a subset of taxa can improve branch support for deep nodes. We initially sequenced ten genes (8,418 bp) for 57 taxa that represent the major lineages of Gracillariidae plus outgroups. After finding that many deep divergences remained weakly supported, we sequenced eleven additional genes (6,375 bp) for a 27-taxon subset. We then compared results from different data sets to assess whether one sampling design can be favored over another. Partially or fully augmenting a data set with more characters increased bootstrap support for particular deep nodes, and this increase was dramatic when non-synonymous changes were analyzed alone. The addition of sites that have low levels of saturation and compositional heterogeneity greatly improved results. We also apply new transcriptome data and examine the effects of adding these data to infer the phylogeny of Gracillariidae.

Systematics, Phylogeny and Zoogeography

The evolutional signal obtained from Afrotropical taxa might significantly change our traditional understanding of the global diversity pattern and phylogeny of Lepidoptera

Jurate De Prins
Royal Museum for Central Africa, Belgium

Our dataset contains 33,541 species group names of moths from sub-Saharan Africa and 44,521 distribution records. With this dataset available online as a searchable website (www.afromoths.net), we aim to disseminate the obtained knowledge and to draw the main guidelines in providing a framework for the understanding of the evolutionary pattern of this model insect group. We stress herewith that the Lepidoptera of sub-Saharan Africa play a prominent role in systematic/biodiversity surveys as indicators of habitat disturbance and biodiversity hotspots. They constitute a mega-diverse group of insects with at the latest count 157,424 recognized species and an additional estimated 230,000 species still to be discovered, mostly in tropical areas. The least known Lepidoptera that include the highest number of undescribed species are the micro-moths, a paraphyletic group ignored by many lepidopterists. Over recent decades, molecular methods have complemented the traditional comparative morphology and taxonomic classification of micro-moths. Furthermore, we studied the taxonomic history of the groups which were treated controversially and in need of explanation, after their primitive position in the phylogenetic clades was established. Field work was carried out for more than 10 years in fast changing African biotopes which are still suitable for primitive moths. In recent years we described more than fifty new species of primitive moths, belonging to the superfamilies Gracillarioidea and Gelechioidea, collected in various parts of sub-Saharan Africa but mainly in primary rain forests of Central Africa. Our future intentions are to clarify the major paths of the geographical dispersal of Afrotropical moth species.

Evolution of pollination behavior and mutualism in *Epicephala* (Gracillariidae)

Atsushi Kawakita
Kyoto University, Japan

Four insect lineages have independently evolved to pollinate their host plants in order to secure food for their seed-consuming larvae. They are the fig wasps, the yucca moths, the senita moth and the Epicephala moths. This intricate behavior has lead to the evolution of remarkable mutualisms between the insect and the plant, where both partners depend totally on each other for reproduction. Epicephala moths are specialized seed feeders of plants in Phyllanthaceae. Adult female Epicephala moths uses their proboscises to actively collect pollen on male flowers and pollinate female flowers, and lay eggs in the flower that she just pollinated. Emerging larvae feed on a fraction of the developing seeds to complete larval development, leaving the rest intact. Extensive observation in the tropics has revealed that this mutualism is widespread globally, with estimated 600 Phyllanthaceae species each pollinated by a species-specific Epicephala. Phylogenetic analysis indicates that the pollination behavior evolved once in Epicephala about 25 Ma. Subsequent diversification of the Epicephala occurred on six distinct lineages of Phyllanthaceae, suggesting that the mutualism evolved multiple times independently in Phyllanthaceae. Some Epicephala species secondarily evolved ability to induce flower galls without needing to pollinate, thus reversing the association from mutualism to pure parasitism.

The genetics of host shifting in a leaf-mining moth *Acrocercops transecta* (Gracillariidae)

Issei Ohshima
Kyoto Prefectural University, Japan

Adaptation to a new environment often requires the evolution of multiple traits, and hybridization between ecologically divergent taxa could produce maladaptive phenotype combinations to result in isolation barriers. In phytophagous insects a precise combination of performance and preference for particular host plants is crucial, and divergence in host associations is considered as a first step of speciation. However, very little is known about the genetic bases of performance and preference traits. Here I show that opposite directions of dominance in performance and preference traits play a key role in host race maintenance in the leaf-mining moth Acrocercops transecta. In this species performance on Juglans is dominant over that on Lyonia, but preference for Lyonia is dominant over that for Juglans. This indicates the genetic components that introgressed from the Lyonia race being removed from the Juglans race, while gene flow will occur from the Lyonia race to the Juglans race. Thus, the different mode of inheritance between performance and preference itself function as an isolating barrier between populations with different host associations. Linkage and QTL analyses revealed that only a restricted region of a single autosome was responsible for the differences in larval performance between the two host races. This indicates that host shifting from Juglans to Lyonia in A. transecta involved changes in a few genes with large effect, suggesting that a few genetic changes in larval-performance loci promoted the successful host shifting.

Ever since Kyrki: A molecular phylogeny for Yponomeutoidea (Lepidoptera, Ditrysia) with new insights into their evolutionary history

Jae-Cheon Sohn[1], Donald Davis[2], Jerome Regier[3], Charles Mitter[4], Jean-Francois Landry[5], Andreas Zwick[6], Michael Cummings[7]

[1]University of Maryland, U.S.A., [2]United States National Museum of Natural History, Smithsonian Institution, U.S.A., [3]University of Maryland, U.S.A., [4]University of Maryland, U.S.A., [5]Agriculture & Agri-Food Canada, Canadian National Collection, Canada, [6]State Museum of Natural History in Stuttgart, Germany, [7]University of Maryland, U.S.A.

Yponomeutoidea represent one of the major radiations in the basal ditrysian Lepidoptera. Yponomeutoidea are especially important for tracing the early evolutionary history of Lepidoptera-plant interactions because they are one of the earliest groups to evolve external feeding (Powell et al., 1998) and to extensively colonize herbs as well as shrubs and trees (Grimaldi and Engel, 2005). Despite its importance to tracing the early evolution of Lepidoptera, the superfamily Yponomeutoidea has been neglected by systematists, and its biodiversity and phylogeny remain poorly understood. Due to the lack of phylogenetic approaches, several researchers have suggested different definitions of Yponomeutoidea which are still in contention. To improve the systematic resolution of Yponomeutoidea, phylogenetic analyses based on 8 to 19 nuclear genes were conducted. The resulting phylogeny shows strong support for monophyly of Yponomeutoidea sensu Kyrki (1990), when the supposed lyonetiid subfamily Cemiostomiinae is excluded. All ten yponomeutoid families as re-defined by van Nieukerken et al. (2011) were strongly supported as monophyletic, if Cemiostomiinae and Scythropia are excluded. Relationships among the families, including deeper splits within Yponomeutoidea, are also mostly well resolved. Our results provide new insights on the circumscription and classification of Yponomeutoidea, and on the evolution of their host plant associations and biogeography.

A preliminary phylogenetic framework of Chalcosiinae (Lepidoptera: Zygaenoidea, Zygaenidae) and the evolution of chemical defense and mimicry

Shen-Horn Yen[1], Chia-Hsuan Wei[2]
[1]National Sun Yat-Sen University, Taiwan, [2]National Sun Yat-Sen University, Taiwan

The chalcosiine zygaenid moths constitute one of the most striking groups within the lower-ditrysian Lepidoptera, with highly diverse mimetic patterns, chemical defence systems, scent organs, copulatory mechanisms, hostplant utilization and diapause biology, plus a very disjunctive biogeographical pattern. A previous study using morphological characters and a very dense taxon sampling strategy reveals that neither the family Zygaenidae nor the subfamily Chalcosiinae is monophyletic. Although the major lineages within the Chalcosiinae sensu stricto are well-supported, the internal relationships between them, however, are still obscure. The present study shows a preliminary results of their phylogenetic analysis using 2 genes from 159 species and 2 Callizygaeninae species as the outgroup taxa. The phylogenetic pattern shows that Agalopini is the sistergroup of the remaining genera. Chalcosiini represents the most derived group with reduced male genitalia and developed A8. Cyclosiini is monophyletic but the sistergroup varies with different analyses. Arbudas is placed with Corma and thus a lineage that was not recovered by morphological analysis is revealed. The new phylogenetic hypothesis can be used to investigate the evolution of specific character sets, such as scent organs of adults, chemical defense, apodemal system of male genitalia, copulatory structures, and sexual dimorphism.

A molecular phylogeny for the pyraloid moths (Lepidoptera: Pyraloidea) and its implications for higher-level classification

Jerome C. Regier[1], Charles Mitter[2], Maria Alma Solis[3], James E. Hayden[4], Bernard Landry[5], Matthias Nuss[6], Thomas J. Simonsen[7], Shen Horn Yen[8], Andreas Zwick[9], Michael P. Cummings[10]

[1]University of Maryland Biotechnology Institute College Park, Maryland, U.S.A., [2]University of Maryland, U.S.A., [3]Agricultural Research Service, United States Department of Agriculture, U.S.A., [4]Florida State Collection of Arthropods, U.S.A., [5]Museum d'histoire naturelle, Switzerland, [6]Museum fur Tierkunde Konigsbrucker Landstr, Germany, [7]The Natural History Museum, Cromwell Road, United Kingdom, [8]National Sun Yat-Sen University, Taiwan, [9]State Museum of Natural History Stuttgart, Germany, [10]Center for Bioinformatics and Computational Biology, University of Maryland, U.S.A.

We present the first detailed molecular estimate of relationships across the subfamilies of Pyraloidea, and assess its concordance with previous morphology-based hypotheses. We sequenced up to five nuclear genes, totaling 6633 bp, in each of 42 pyraloids spanning both families and 18 of the 22 subfamilies, plus up to 14 additional genes, for a total of 14,826 bp, in 22 of those pyraloids plus all 24 outgroups. Maximum likelihood analyses yield trees that differ little among data sets and character treatments and are strongly supported at all levels of divergence. Subfamily relationships within Pyralidae, all very strongly supported, differ only slightly from a previous morphological analysis, and can be summarized as Galleriinae + Chrysauginae (Phycitinae (Pyralinae + Epipaschiinae)). In Crambidae the molecular phylogeny is also strongly supported, but conflicts with most previous hypotheses. Among the newly-proposed groupings is a "wet-habitat clade" comprising Acentropinae + Schoenobiinae + Midilinae, and a provisional "mustard oil clade" containing Glaphyriinae, Evergestinae and Noordinae, in which the majority of described larvae feed on Brassicales. Within this clade a previous synonymy of Dichogaminae with the Glaphyriinae is supported. Evergestinae and Noordinae are synonymized with Glaphyriinae, which appear to be paraphyletic with respect to both. Pyraustinae and Spilomelinae as sampled here are each monophyletic but form a sister group pair. Wurthiinae comprising the single genus Niphopyralis Hampson, which lives in ant nests, are closely related to, apparently subordinate within, and synonymized with, Spilomelinae.

Phylogenetic and comparative studies of tiger moths (Lepidoptera: Erebidae)

Jennifer M. Zaspel[1], Taylor Ward[2], Stacey Coy[3], Kendra Casanova[4], Susan Weller[5]

[1]Purdue University, U.S.A., [2]University of Minnesota, U.S.A., [3]University of Wisconsin Oshkosh, U.S.A., [4]University of Wisconsin Oshkosh, U.S.A., [5]University of Minnesota, U.S.A.

Despite the important role of tiger moths in chemical ecology and behavioral studies, few molecular investigations of arctiine phylogeny exist. Preliminary molecular studies support the monophyly of Arctiini, Lithosiini, and Syntomini but do not support the limits of all subtribes within Arctiinae. To test the monophyly of tiger moth subtribes and address the evolution of tiger moth life history traits, a phylogenetic hypothesis of Arctiinae was generated based on DNA sequence data from 4 genes for 70 taxa. We examined origins of pyrrolizidine alkaloid (PA) associations and the evolution of PA pharmacophagy in adults. This study also investigated whether specialized proboscis structures are associated with adult pharmacophagy.

Repeated evolution of early and late winter geometrid moths

Satoshi Yamamoto[1], Eugene A. Beljaev[2], Teiji Sota[3]
[1]Kyoto University, Japan, [2]Russian Academy of Science, Russia, [3]Kyoto University, Japan

Diversification during Quaternary climatic oscillation is demonstrated in various taxa. The refugial isolation hypothesis, which is geographic isolation by restricted gene flow between different refugia, has been widely supported as a mechanism of diversification during cool climatic period. This indicates dominant role of refugial isolation during climatic oscillation. Wide acceptance of refugial isolation hypothesis may dependent on easiness to detect the records of past distribution. Other speciation mechanism would also contribute to diversification in Quaternary. Our previous works demonstrated that a winter geometrid moth is diverged in cool habitat by differentiation of reproductive season whereas are not differentiated in warm habitat. It indicates that intensive climate oscillation in Quaternary causes diversification of winter geometrid moths. Here we show that a winter moth genus, Inurois, have been diversified by repeated differentiation of reproductive season and hybridized between the species with different reproductive seasons in Quaternary. This result is compatible with the hypothesis. Moreover, our result suggests that two early winter moths, which diverge from different lineages, united into single species, suggesting the important role of climatic oscillation than geographic isolation. Our results suggest that the diversification during Quaternary climatic oscillation is needed to study from various perspectives.

Biogeography of the Pedaliodine complex: Are Pedaliodes complex genera consequence of horizontal or vertical events of reproductive isolation?

Giovanny Fagua[1], Monica Higuera[2], Luz Angela Galindo-Leva[3]
[1]Pontificia Universidad Javeriana, Colombia, [2]Pontificia Universidad Javeriana, Colombia, [3]Scientia Colombia SAS, Colombia

The Pedaliodes species complex is one of the most diverse groups of butterflies. With over 270 species and 17 genera, the majority of these species to be found in the high Andean mountain (over 2000 m altitude). In 1986, Adams proposed a model to explain the diversification of the group, based on the altitudinal migration of different vegetation types in the Andes during the Pleistocene glaciations. However, a phylogenetic analysis based in morphology and the geographical distribution of these butterfly species suggests a closer connection to the horizontal expansion and reduction of forests and other types of vegetation areas in South America during the Pleistocene, in the sense of the Refuge Pleistocene Theory of Haffer (1969). To produce the phylogeny, we analyzed 17 genera and 45 species of the complex. The phylogenetic analysis (TNT) produced only one obtained tree (555 steps, CI= 0.23, RI= 0.53). Major conclusions were: the Pedaliodes complex is a monophyletic group, where the genus Dangond was the sister group of the other genera of the Pedaliodes complex. Out of the 17 genera covered in the present study, just Panyapedaliodes, Pherepedaliodes, Praepronophila, Redonda, and Steromapedaliodes, were natural groups. As a consequence, both, a phylogeny obtained on morphological evidence and the geographical distributions of the valid genera, are closer with the process of horizontal geographical isolation than with the vertical geographical isolation process.

Molecular systematics of the butterfly tribe preponini (Nymphalidae: Charaxinae)

Elena Ortiz-Acevedo[1], Keith R. Willmott[2]

[1]University of Florida, U.S.A., [2]McGuire Center for Lepidoptera and Biodiversity - University of Florida, U.S.A.

The nymphalid butterfly tribe Preponini includes some of the most spectacular Neotropical butterflies, but their taxonomy remains poorly resolved. Recent studies of Nymphalidae phylogeny have suggested that both the tribe and several genera might not be monophyletic, but to date taxon sampling has not been sufficiently comprehensive to allow informed revision of the group's systematics. We therefore conducted the first complete species-level phylogenetic study of the tribe to establish a firm higher classification. We used DNA sequence data from three genes, two mitochondrial genes, Cytochrome Oxidase subunits I and II (COI and COII), and the nuclear gene, Elongation Factor - 1 alpha (EF-1α), to reconstruct the phylogeny of the tribe using Maximum Likelihood (ML), Maximum Parsimony (MP), and Bayesian Inference (BI). We included 48 individuals representing the 22 recognized Preponini species, and 25 outgroup taxa to explore taxonomic limits at different levels. Firstly, we found that Anaeomorpha splendida Rothschild, 1984 never formed a clade with remaining Preponini, so that maintaining monophyly of the tribe requires Anaeomorpha's exclusion and we thus reinstate the tribe Anaeomorphini [stat. rev.]. Secondly, we investigated generic limits, in particular the relationship of Noreppa Rydon, 1971 to Archaeoprepona Fruhstorfer, 1915, and Agrias Doubleday, [1845] to Prepona Boisduval, 1836. The molecular results coupled with previous morphological studies suggest that Noreppa should be synonymized with Archaeoprepona [stat. rev.] and Agrias with Prepona (syn. nov.). This study also found a number of cases of significant DNA sequence divergence and paraphyly or polyphyly within putative species that require further taxonomic attention.

Timing the diversification of beetles (Coleoptera)

Duane D. McKenna[1], Alex Wild[2], Kojun Kanda[3], David Maddison[4], Brian D. Farrell[5]

[1]University of Memphis, U.S.A., [2]University of Illinois Urbana-Champaign, U.S.A., [3]Oregon State University, U.S.A., [4]Oregon State University, U.S.A., [5]Harvard University, U.S.A.

Beetles (Coleoptera) exhibit extraordinary ecological and taxonomic diversity. However, our understanding of the evolutionary history of this diversity is in its infancy. This is in large part due to the lack of a relatively comprehensive and well-supported phylogeny for beetles. In this presentation I will present a brief overview of beetle macroevolution based on analyses of DNA sequence data conducted as part of the Beetle Tree of Life Project. Specifically, I will present evidence for the rapid radiation of beetle suborders and for the timing of origin and diversification of select beetle families and certain other higher-level taxonomic groups. I will briefly discuss the timing of beetle diversification relative to major events in earth's history, including the rise of flowering pants to ecological dominance.

Evolution of cleptoparasitic strategy in the bee family Megachilidae

Jessica R. Litman[1], Terry L. Griswold[2], Bryan N. Danforth[3]

[1]Cornell University, U.S.A., [2]Utah State University, U.S.A., [3]Cornell University, U.S.A.

While the majority of solitary bees are nest-building, a number of lineages are recognized as cleptoparasites. These so-called "cuckoo bees" neither build nor provision their own nests but rather lay their eggs in nests prepared by a host bee. In general, the pollen stored in the nest of the host is not sufficient to sustain the development of both the host larvae and those of the cleptoparasite; in order to eliminate the competition for resources presented by the hosts' larvae, the cleptoparasite usually kills the hosts' larvae. To this end, cleptoparasitic bees have evolved two distinct strategies. In the first, the adult female cleptoparasite removes or kills the host eggs and larvae; in the second, one or more cleptoparasitic larval instars, highly aggressive and often armed with long sharp mandibles, kill the host eggs and larvae. While cleptoparasitic lineages typically display either one strategy or the other, certain lineages in the bee family Megachilidae appear to contain both modes of cleptoparasitism. We assembled a large, multi-locus dataset for Megachilidae and used this family as a model system to trace the evolution of cleptoparasitic strategy, as well as the evolutionary transition between nest-building bees and cleptoparasites. The results of maximum likelihood and Bayesian-based analyses reveal a clear pattern in the evolution of cleptoparasitic behavior; our results also indicate a correlation between the ages of cleptoparasitic clades and the strategies they employ.

Divergence time estimates for therevoid flies (Diptera: Asiloidea)

Shaun Winterton[1], Jessica Ware[2]

[1]California State Collection of Arthropods, U.S.A., [2]Rutgers, New Jersey, U.S.A.

Divergence time estimates can be influence by the inclusion of fossils in morphological data. We present the results of a phylogenetic analysis and and divergence time estimates for four families of asiloid flies representing the therevoid clade: Scenopinidae, Apsilocephalidae, Evocoidea and Therevidae. By combining morphological and molecular data we explore the effects of inclusion of different fossil taxa on phylogram topology and divergence time estimation. Fossil taxa include representative of three of the four families from Mesozoic and Cretaceous age amber deposits, including a putative stem group taxon from Burmese amber.

300 millions of evolution: Divergence dating in Orthoptera (Arthropoda: Insecta)

Hojun Song
University of Central Florida, U.S.A.

With more than 23,000 valid species, Orthoptera is the most diverse member of the group of polyneopteran insect orders. Despite the familiarity, the phylogenetic relationships within Orthoptera are poorly understood because of a long history of conflicting taxonomic classification schemes based on different character sets. In this presentation, I present a robust higher-level phylogeny of Orthoptera based on complete mitochondrial genomes and four nuclear genes. Using the extensive fossil evidence known from the Carboniferous to the Tertiary, I estimate divergence time for the major groups within the order. The analysis suggests that the current diversity of Orthoptera is a result of both gradual and rapid radiation followed by a number of extinctions. The current distribution is a result of both deep vicariance and recent dispersal. Therefore, the divergence dating reveals a dynamic evolutionary history of this fascinating group of insects.

Systematics, Phylogeny and Zoogeography

Wing base morphology and phylogeny of Paraneoptera

Kazunori Yoshizawa
Hokkaido University, Japan

The wing base structure of insects is composed of many sclerites located between the notum and wing. Very sophisticated wing movements (flapping and folding) are achieved by these sclerites, and slight modification of these sclerites can make insects flightless. Because of these constraints, this structure is known to evolve very slowly. Thus, the wing base structure should contain useful phylogenetic information for uncovering deep insect divergence. Characters selected from the wing base have been applied to estimating the higher level phylogeny of Paraneoptera. These studies have provided support for Paraneoptera + Holometabola (Yoshizawa, 2011: Syst. Ent.), monophyly of Paraneoptera, Thysanoptera + Hemiptera (= Condylognatha), Fulgoromorpha + Cicadomorpha (= Auchenorrhyncha) (Yoshizawa & Saigusa, 2001: Syst. Ent.), monophyly of Cicadomorpha, and Cicadoidea + Cercopoidea (Yoshizawa & Wagatsuma, in press: Ent. Sci.). Most of these relationships have also received support from molecular phylogenies, but monophyly of Paraneoptera has not been recovered using molecular evidence. Support values for non-monophyly of Paraneoptera from the molecular data are typically weak, whereas the wing base characters provided a total of 9 non-homoplasious autapomorphies of Paraneoptera. Therefore, monophyly of Paraneoptera can be regarded as highly plausible and deserves further examination using additional molecular data.

Mitochondrial genomics of Paraneoptera

Stephen L. Cameron
Queensland University of Technology, Australia

The mitochondrial genome of insects is remarkably stable through evolutionary time, with rearrangements uncommon in almost all orders. The Paraneoptera are the great exception to this stability ? major rearrangements (those involving protein-coding or rRNA genes) have been recorded in all 4 paraneopteran orders. The majority of Hemiptera species examined to date are not rearranged, however a series of synapomorphic rearrangements are found in whiteflies (Aleyrodidae). The single Thysanoptera mt genome sequenced is high rearranged. The greatest diversity of genome arrangements and structures occurs in the Psocoptera/Phthiraptera where there is an evolutionary trend towards increasing rates of genome rearrangement and the evolution of a multichromosomal mt genome. The evolution of mt genomes within the Paraneoptera and the underlying genetic causes will be discussed.

A timescale for the evolution of lice

Vincent Stuart Smith[1], Kevin P. Johnson[2], Kazunori Yoshizawa[3], Jessica E. Light[4]

[1]The Natural History Museum, United Kingdom, [2]University of Illinois, U.S.A., [3]Hokkaido University, Japan, [4]Texas A&M University, U.S.A.

In the past decade substantial progress has been made at resolving the phylogeny of parasitic lice (Insecta: Phthiraptera). Much of this work has been driven by a desire to compare the phylogenetic histories of lice with their obligate avian and mammalian hosts. These studies have identified a number of louse taxa that show evidence of cospeciation with their hosts. Cospeciation events are important as they provide an internal time calibration on the evolution of lice. The recent discovery of two important fossils shed light on the age of lice, independent of their hosts. In this presentation I review recent work that use these cospeciation and fossil calibration points, together with data from multiple genetic markers, to establish the age of the major lineages of parasitic lice. These data demonstrates that the major families of lice began to radiate before the K?Pg boundary. The diversification of extant chewing lice parasitizing mammals postdates the K?Pg boundary, in contrast to the Cretaceous diversification of their avian infesting relatives. This suggests parasitic chewing lice were first acquired by birds and later diversified on mammals. Parasitic lice use their host's pelage or plumage as both a habitat and a food resource and host specificity can be attributed to phenotypic variation of host hair and feathers. Given the diversification times presented here and the early origin of feathers, parasitic lice probably infested feathered theropod dinosaurs.

Phylogenomics of lice using next-generation sequencing

Kevin Paul Johnson[1], Kimberly Walden[2], Hugh Robertson[3]
[1]University of Illinois, U.S.A., [2]University of Illinois, U.S.A., [3]University of Illinois, U.S.A.

New DNA sequencing methods can produce billions of base pairs of DNA sequence in a highly automated fashion for a fraction of the costs of traditional targeted sequencing. These technologies have incredible potential for providing genomic scale data sets for phylogenomic analysis. A Target Restricted Assembly Method (TRAM) was applied to Illumina sequence reads for 20 species of Psocodea using the human body louse (Pediculus humanus) as a reference. These reads were mined and assembled for genes proven to be 1:1 orthologs across insect genomes sequenced to date. A phylogenomic data set was produced and analyzed for a small sample of the 1024 potential ortholog genes. Analyses of these data indicated that mammalian Ischnocera (Trichodectidae) are sister to other mammalian lice (Rhynchophthirina and Anoplura), making Ischnocera paraphyletic. Parasitic lice were also paraphyletic, indicating multiple origins of parasitism. These analyses indicate considerable potential for next-generation sequencing technologies to be used to generate genomic scale data sets, even when material not suitable for RNA extraction is used.

Thripin' Awesome: Phylogeny and mitochondrial genomics of Thysanoptera

Rebecca Buckman[1], Laurence Mound[2], Michael Whiting[3]

[1]Brigham Young University, U.S.A., [2]CSIRO, Australia, [3]Brigham Young University, U.S.A.

Encompassing nearly 6,000 species, Thysanoptera has two suborders (Tubulifera and Terebrantia) with nine extant families but their phylogenetic relationships are poorly understood. Here, five genetic loci (18S, 28S, Histone 3, Cox I, and Tubulin alpha 1) for 101 species representing six of the nine extant thrips families. Trees were reconstructed using parsimony and model-based methods for the combined data set. Thrips are suspected of having a high degree of rearrangement within the mitochondrial genome, two mitochondrial genomes were sequenced using 454 pyro-sequencing for one Tubuliferan species and one Frankliniella species. The objectives of this study were to (1) test the monophyly of the suborders Tubulifera and Terebrantia; (2) elucidate relationships among the thrips families; and (3) investigate the evolution of gene rearrangements in the mitochondrial genome. Our analyses strongly support the monophyly of both suborders Tubulifera and Terebrantia. Phlaeothripidae Aeolothripidae, Melanthripidae and Thripidae are all monophyletic. The relationship between Aeolothripidae and Merothripidae to the rest of Terebrantia is equivocal. Four of the six subfamilies are recovered as monophyletic. The two largest subfamilies, Phlaeothripinae and Thripinae, are paraphyletic and require further study to understand relationships within them. Patterns of mitochondrial genome rearrangements in light of relationships are suggestive of strong phylogenetic signal in gene rearrangements.

Phylogeny and evolution of Aphidini (Sternorrhyncha)

Hyojoong Kim[1], Seunghwan Lee[2]
[1]*Kunsan National University, Republic of Korea,* [2]*Seoul National University, Republic of Korea*

Aphids (Hemiptera: Aphididae) are well known as micro-insect pests, which are very specific to their host plants, and most of them have successfully maintained parthenogenetic generations cyclically or permanently. In the world, the approximately 5,000 described aphid species belong to the family Aphididae. The diversification of host plants, especially angiosperms, has played an important role in their evolution. Here, I would like to present macroevolutionary patterns of three major aphid groups, Aphidini, Macrosiphini, and Pterocommatinae, which are the most diverse in the world and constitute more than 60% of the total species. These major lineages demonstrate the evolutionary history of aphids interacting with their host plants. Major questions about aphid evolution include origins of host alternation as well as age and patterns of diversification in relation to host plants. To address these questions, we reconstructed the phylogeny using a combined dataset of one nuclear and four mitochondrial DNA regions. A molecular dating approach, calibrated with fossil records, was used to estimate divergence times of these taxa. Based on phylogenetic and dating analyses, most generic divergences in Aphidinae occurred in the Middle Tertiary when primary hosts, mainly Rosaceae, were diverging, whereas species-level divergences were related with diversification of secondary hosts such as Poaceae in the Middle to Late Tertiary. Most generic divergences in Aphidini occurred in the Middle Tertiary, and species-level divergences occurred between the Middle and Late Tertiary. My presentation will be mainly focused on the evolution of host alternation and co-diversification between aphids and their host plants.

Paraneoptera: Traits and evolution of wing venation pattern

Andre Nel[1], Jakub Prokop[2], Patricia Nel[3], Philippe Grandcolas[4], Di-ying Huang[5], Jacek Szwedo[6]

[1]CNRS UMR 7205, Museum National d'Histoire Naturelle, CP 50, Entomologie, 45 rue Buffon, F75005 Paris, France, [2]Charles University in Prague, Faculty of Science, Vinicna 7, CZ-128 44, Praha 2, Czech Republic, [3]CNRS UMR 7205, Museum National d'Histoire Naturelle, France, [4]CNRS UMR 7205, Museum National d'Histoire Naturelle, France, [5]Nanjing Institute of Geology and Palaeontology, Chinese Academy of Sciences, China, [6]Museum and Institute of Zoology, Polish Academy of Sciences, Poland

Monophyly of Paraneoptera is widely accepted, but two different patterns of wing venation are currently supposed to be present in each of the three major groups (Psocodea, Thripida, Hemiptera). This is unlikely compared to the situation in other insects where only one pattern exists per order. We propose for all Paraneoptera a new interpretation of wing venation pattern, assuming that the convex CuA gets fused with the common stem of median and radial veins at or very near to wing base, after separation from concave CuP, and re-emerges more distally from R+M stem. Thereafter, the vein between concave CuP and CuA is a specialized crossvein called 'cua-cup', proximally concave and distally convex. We show that despite some variations, i.e. cua-cup can vary from absent to hypertrophic; CuA can re-emerge together with M or not, or even completely disappear, this new interpretation explains all situations among all fossil and recent paraneopteran lineages. We propose that the characters 'CuA fused in a common stem with R and M' and 'presence of specialized crossvein cua-cup' are venation apomorphies that support the monophyly of the Paraneoptera. In the light of these characters we re-interpret several Palaeozoic and early Mesozoic fossils that were ascribed to Paraneoptera, and confirm the attribution of several to this superorder, as well as possible attribution of Zygopsocidae (Zygopsocus permianus Tillyard, 1935) as oldest Psocodea. We discuss the situation in extinct Hypoperlida and Miomoptera, suggesting that both orders could well be polyphyletic, with taxa related to Archaeorthoptera, Paraneoptera, or even Holometabola.

Systematics, Phylogeny and Zoogeography

Phylogeny of Hemiptera based on the sequences of mitochondrial genomes

Wenjun Bu
Nankai University, China

Hemiptera is the largest order in Paraneoptera and the fifth largest in Insecta. Disputes about hemipteran phylogeny have long focused on the monophyly of Auchenorrhyncha or the relationships between the suborders Fulgoromorpha, Cicadomorpha, Coleorrhyncha and Heteroptera. Two mitochondrial genomes of Coleorrhyncha were provided in this study. All suborders of Hemiptera were smampled in the study. Two types of data, amino acid sequences and nucleotides of various combinations between protein coding genes, tRNAs and rRNAs of mitochondrial genomes, were used to infer the phylogeny of Hemiptera. In total 27 taxa of Paraneoptera were sampled, 24 of them being hemipterans. Three different phylogenetic methods, Bayesian inference, maximum likelihood and maximum parsimony analyses, were employed. The results question the the monophyly of Homoptera and Auchenorrhyncha. The relationship of Cicadomorpha + Heteroptera is always stable in the results with different combinations between data types and phylogenetic methods. In evaluating the relative contribution of each gene, the phylograms generated by single genes, CO1, ND1, ND2, ND4 and ND5 respectively, well matched the tree yielded from the combined datasets. In light of the taxon-sampling sensitivity of trees based on mitochondrial genomes, the results need to be tested with more data from nuclear genes.

Systematics, Phylogeny and Zoogeography

Phylogeny of Heteroptera - combined morphological and molecular perspective

Christiane Weirauch[1], Randall T. Schuh[2], Ward C. Wheeler[3]

[1]University of California Riverside, U.S.A., [2]American Museum of Natural History, U.S.A., [3]American Museum of Natural History, U.S.A.

With more than 40,000 described species in 86 families and 7 infraorders, Heteroptera or "true bugs" are one of the megadiverse phylogenetic lineages of animals. Their morphological and ecological diversity rivals any suprafamilial group of insects as shown by their successful occupation of most major ecosystems on Earth ? they skim the surface of the open oceans, live as temporary and permanent ectoparasites in the fur of bats, are kleptoparasitic on spider webs, and are detritivores on the tops of active volcanoes. Phylogenetic hypotheses are pivotal for understanding heteropteran diversity and essential for testing current classifications and evolutionary hypotheses. We here present the first combined morphological and molecular phylogenetic analysis of Heteroptera since the combined study by Wheeler, Schuh, and Bang (1993). This analysis aims on investigating recently proposed relationships, among them the potential sister-group relationship of Nepomorpha, the aquatic bugs, with all remaining Heteroptera. In addition, we present a combined molecular and morphological analysis that focuses on examining relationships within the Cimicomorpha, the largest heteropteran infraorder, with emphasis on the position of Pachynomidae and monophyly of Nabidae. We conclude that incorporating morphological data into large-scale phylogenies has never been more important.

Evolution of traumatic insemination in cimicoid true bugs

Sunghoon Jung[1], Ondrei Balvin[2], Kazutaka Yamada[3], Seunghwan Lee[4]

[1]University of California Riverside, U.S.A., [2]Faculty of Science, Charles University, Czech Republic, [3]Tokushima Prefectural Museum, Japan, [4]Seoul National University, Republic of Korea

Traumatic insemination (TI), an extraordinary copulation strategy, is most prevalent in cimicoid true bugs (Insecta: Hemiptera) among invertebrates including insects. As evolutionary defensive mechanisms, not only a number of cimicoid females, but some males in response to homosexual mating attempts have evolved special morphological structures, the paragenital system (PS), which is known to reduce physical damage and increased risk of bacterial infection associated with TI. However, some cimicoids do not have developed PS despite of being engaged in TI. Here, we resolved the evolutionary history of TI and the females' adaptations by conducting molecular phylogenetic analyses and comparative studies based on the phylgenetic relationships. We found a sister group relationship of Curaliidae + Lasiochilidae, which are the only groups among Cimicoidea that are likely in non-TI. Divergence time estimates revealed that TI is a behavior of antiquity that first evolved in the Early Jurassic 188Mya (95% highest posterior density = 157-221). Furthermore, ancestral character state reconstructions indicated that TI evolved only once from standard insemination in Cimicoidea. To investigate whether TI evolution might have been related to other unique biological traits of cimicoids such as parasitism, and to test the hypothesis of correlation between TI and PS, correlation tests and contingency analyses were conducted. The results revealed that only TI is correlated with PS among the biological traits, and that evolutionary acquisition of PS was driven by selection of TI. This study also suggests convergent evolution of the females' morphology (PS) have occurred as females were adapting to TI.

Vertical transmission and cospeciation of gut symbionts in heteropteran stinkbugs

Takahiro Hosokawa[1], Yoshitomo Kikuchi[2], Nahomi Kaiwa[3], Takema Fukatsu[4]

[1]National Institute of Advanced Industrial Science and Technology (AIST), Japan, [2]National Institute of Advanced Industrial Science and Technology (AIST), Japan, [3]The University of Tokyo, Japan, [4]National Institute of Advanced Industrial Science and Technology (AIST), Japan

Many insects harbor mutualistic bacterial symbionts endocellularly in the specialized symbiotic organ, called bacteriome, and vertically transmit the symbionts from females to offspring. In such insect groups as aphids, tsetse flies, weevils, etc., molecular phylogenetic analyses have shown that the symbionts are monophyletic and the symbiont phylogeny mirrors the host phylogeny, suggesting a single bacterial infection in the common ancestor and subsequent host-symbiont cospeciation. The majority of plant-sucking stinkbugs (Heteroptera: Pentatomomorpha) do not possess the bacteriome but harbor bacterial symbionts extracellularly in the lumen of the midgut crypts. The symbiotic associations are generally mutualistic, wherein symbiont-deprived nymphs suffer high mortality, retarded growth, and/or reduced body size. Stinkbugs of the superfamily Pentatomoidea vertically transmit their gut symbionts by either of the post-hatch mechanisms, egg surface contamination, coprophagy, and symbiont capsule provisioning. Notably, recent studies have revealed that different pentatomoid families exhibit distinct evolutionary patterns in their host-symbiont intimacy. In the families Acanthosomatidae, Plataspidae and Urostylidae, the gut symbionts formed a monophyletic group and cospeciated with their hosts. In the families Cydnidae, Pentatomidae and Scutelleridae, by contrast, the gut symbionts are polyphyletic and exhibit no host-symbiont co-speciation, suggesting occasional symbiont acquisitions and/or replacements in their evolutionary course. Comparative studies on these stinkbugs, their gut symbionts, and interactions between them would provide novel insights into various evolutionary aspects of the mutualistic gut symbiotic associations. We argue these evolutionary patterns in relation to the anatomical traits of their symbiotic systems and the mechanisms for vertical transmission of their gut symbionts. [Supported by BRAIN]

The Flytree of life: Resolution and radiation of higher- level fly phylogeny

Brian M. Wiegmann
North Carolina State University, U.S.A.

FLYTREE is a consortium of world dipterists engaged in a collaborative research project initiated by the US National Science Foundation Assembling the Tree of Life (AToL) program. During its six-year funding term, this project combined the efforts of over 19 laboratories in 6 countries. Data collection and phylogenetic analyses were divided in tiers: Tier 1 includes 45 species across the order and several outgroups sampled for approximately 30kb of aligned genetic data from 14 nuclear genes, full mitochondrial genomes and 371 scored morphological features; Tier 2 includes 202 taxa comprising at least one species from nearly all families, sampled for 5 nuclear genes. Combined molecular data from the 1st and 2nd Tiers form the largest matrix yet completed for Diptera. Tier 3 studies involve detailed phylogenetic analysis within dipteran clades achieved through a network of interacting research programs. These studies enabled 30+ published phylogenetic studies that treat over 1000 fly taxa for molecular and/or morphological data. Here, major findings of the FLYTREE project are presented, highlighting specific hypotheses about the origin, age, and diversification of fly lineages and emphasizing modern approaches in large dataset construction and analysis. Remaining questions serve to direct, guide, and focus the search for new evidence from genomic data harvests and morphological surveys. The FLYTREE project continues through the shared research activities of the Diptera systematics community and provides a successful model for research collaboration toward resolution of complex and hyperdiverse areas of the tree of life.

The Flytree morphology: A new phylogenetic estimate from exemplar-based analysis across the order

David Yeates
CSIRO Ecosystem Sciences, Australia

The Diptera are one of the largest insect Orders, with over 150,000 described species in over 10,000 genera classified in 150 recognised families. FLYTREE is a large international consortium funded by the US National Science Foundation's Assembling the Tree of Life initiative to estimate Dipteran phylogeny. FLYTREE has assembled the largest supermatrices of Diptera, including both molecular and morphological components. 371 morphological characters scored for 42 exemplar fly species spanning the order, and mecopteran outgroups. Trees based on non-additive parsimony analysis of the morphological supermatrix largely confirm Hennig and other author's previous findings, and are consistent with mixed-model Bayesian analysis of concatenated molecular sequences. Well-supported clades (Bremer Support indices > 10) include Diptera, Brachycera, Cyclorrhapha, Schizophora, Calyptrata and Oestroidea. The Nematocera, Orthorrhapha, Aschiza and Acalyptrata are found to be paraphyletic, and support for relationships in these regions of the tree is also poor. The results suggest rapid bursts of fly diversification at the end of the Permian, in the Jurassic, and at the Cretaceous/Tertiary boundary.

Reciprocal illumination between morphology and molecules in basal Diptera phylogeny

Dalton de Souza Amorim
Universidade de Sao Paulo, Brazil

Morphology and molecules quite frequently result in conflicting topologies?as also different partitions of morphological or molecular data. This is good. Incongruence is useful in terms of compelling reexamination of prior assumptions. The molecular phylogeny of Diptera published by Wiegmann and collaborators in 2011 conflicts in some extent with older molecules philogenies?e.g., about the position of the Tipulomorpha, the Scatopsoidea and other groups. Some of the new molecular hypotheses are largely congruent with information, e.g., from thorax morphology, but there are still important conflicts. There is strong evidence that a single event of detachment of the meron from the midcoxa occurred?a major change in the evolution of thorax morphology in Diptera?, a feature plesiomorphic in Tipulomorpha (including Trichoceridae), Bibionomorha (including Anisopodoidea and excluding Scatopsoidea), and Culicomorpha, but derived in Brachycera, Psychodomorpha and Blephariceromorpha. On the other hand, the exclusion of "Manotidae" from the Mycetophilidae based on molecular data was surprising at a first sight. Reexamination of the wing venation of the plesiomorphic genus Paramanota shows a long, complete cubital fork, a feature derived in almost all mycetophilids?showing that in this case morphology may have been wrong in the past. Clades of the basal Diptera in the new molecular phylogeny are analyzed about their support in morphological evidence. A closer contact between morphology and molecule data shortens the path to more robust phylogenies. This does not mean only total evidence, but especially reciprocal illumination for double checking ad hoc hypotheses of homology in morphology and molecular data.

Molecular phylogeny of dark-winged fungus gnats (Diptera: Sciaroidea: Sciaridae) and the evolution of larval feeding habits

Seunggwan Shin[1], Sunghoon Jung[2], Frank Menzel[3], Kai Heller[4], Heungsik Lee[5], Seunghwan Lee[6]

[1]Seoul National University, Republic of Korea, [2]University of California, Riverside, U.S.A., [3]Leibniz-Zentrum fur Agrarlandschafts- und Landnutzungsforschung (ZALF), Germany, [4]Arthur-Zabel-Weg 25, D-24226 Heikendorf, Germany, [5]National Plant Quarantine Service, Republic of Korea, [6]Seoul National University, Republic of Korea

We present the first molecular phylogeny of the Sciaridae. This phylogeny is based on maximum likelihood, maximum parsimony, and Bayesian analyses of 4,809 base pairs (bp) of DNA sequences from two mitochondrial (COI and 16S) and two nuclear (18S and 28S) genes for 100 taxa including the outgroup. According to the present phylogenetic analyses, Sciaridae involve three subfamilies and two genus groups: Sciarinae, Cratyninae, Megalosphyinae, Lycoriella group, and Chaetosciara group. Molecular results are largely congruent with former hypotheses based on morphological data with respect to the monophyly of genera and subfamilies (Sciarinae, Megalosphyinae, and part of "Lycoriellinae") sensu Menzel and Mohrig (2000). However, the subfamily Cratyninae sensu Menzel and Mohrig (2000) could be paraphyletic and the Chaetosciara group is separated from the subfamily Sciarinae sensu Menzel and Mohrig (2000). Bradysia, Corynoptera, Leptosciarella, Lycoriella, and Phytosciara could be paraphyletic groups. Furthermore, the ancestral larval feeding state reconstruction based on Bayesian inference was saproxylic (detritophagous + xylophagous) for the Sciaridae. In contrast, the larval feeding habits of the common ancestors of Phytosciara and Bradysia were inferred to be phytophagous. Therefore, shifts in larval feeding habits from saproxylic to phytophagy occurred within the Sciaridae at least twice.

Phylogeny and biodiversity of therevoid flies (Diptera: Asiloidea)

Shaun Winterton
California State Collection of Arthropods, U.S.A.

Four families of asiloid flies comprise the therevoid clade: Scenopinidae, Apsilocephalidae, Evocoidea and Therevidae. Previous investigations into understanding the evolutionary history of this group have been piece-meal and focused on adult morphology, molecular sequence data and even include a super-tree analysis. Despite this, our knowledge of the group is still fragmentary. A summary of our knowledge of therevoid clade phylogeny is presented, including results of recent large-scale analyses of combined molecular and morphological data, including estimates of divergence times including fossil taxa. Relationships among the families and subfamilies of Scenopinidae and Therevidae are examined using statistical measures. Therevidae represent the bulk of species level diversity in the clade, with numerous new species being described presently, especially from the Australasian region. Results of cybertaxonomic studies attempting to describe this species rich fauna expediciously are presented.

Biol. and Genetic Engineering (CBMEG), State University of Campinas (UNICAMP), Brazil

The order Diptera represent 12‰ of the insects biodiversity described, including species adapted to different environments, acting as pathogen vectors, parasites, decomposers and pollinators, in addition to model organisms. Despite exponential increase of sequencing datasets, arthropods have been omitted from recent genomic studies. With the availability of the new small-scale genome sequencing instruments from Ion Torrent (Personal Genome Machine) and Illumina (MiSeq) we generated the complete mitochondrial DNA (mtDNA) from long-PCR products of 24 fresh and preserved specimens of Schizophora clade (Diptera: Brachycera) under the same pipeline for data production and analysis. The assemblings were generated with >300 thousand reads for each species, producing a coverage of >2500X of the mtDNA. The mitochondrial genome is the most used molecular marker in evolutionary studies in metazoans, but the access to the whole sequence in different species under the same pipeline is not widespread, reflecting the diversity and difficulties in the DNA attainment of small samples and preserved specimens. The use of this approach in a broad range of species can lead the mitogenomics of invertebrates to a new standing, providing a high number of characters to be applied in evolutionary studies, molecular identification, specific primer design and increasing the assessment of the genetic diversity in different taxonomic levels. The application of these technologies enables to rapidly move from comparative genomic studies to population genomics of this important order, which plays a significant role in human health and the environment.

Outgroup relationships, basal phylogeny and classification of the family Tephritidae

Ho-Yeon Han[1], Kyung-Eui Ro[2]

[1]Yonsei University, Republic of Korea, [2]Yonsei University, Republic of Korea

The fly family Tephritidae (Diptera) contains some of the most significant agricultural pests in the world and has some importance as a source taxon for the biological control of weeds. A well-defined phylogeny of the major lineages within this important family is presently lacking and is essential for further research on these flies. At present, six subfamilies are recognized, each containing a number of different tribes. However, characters defining these taxa are often weak, the relationships among the taxa are undefined, and classification schemes do not serve as a predictor of evolutionary relationships. Our molecular data already have significantly contributed toward the sound classification of the family Tephritidae. Some of the examples of such contributions are the confirmations of the following systematic hypothesis based on the sequences of 16S rRNA, 12S rDNA, COI and COII genes: (1) two monophyletic groups within the superfamily Tephritoidea were clearly recognized they are compatible with Willi Hennig's Pallopteroidea and Otitoidea that are not used in the contemporary higher classification; (2) a sister group relationship between Ortalotrypeta and Tachinisca, and their basal phylogenetic position within Tephritidae (3) a sister group relationship between the tribe Acanthonevrini and Phytalmiini; (4) monophyly of Taomyia plus an undescribed new genus, and their sister group relationship with the subfamily Tephritinae; (5) a possible sister group relationship of Cephalophysa and Adramini; and (6) reconfirmation of monophyletic Trypetini, Carpomyini, Tephritinae, and Dacinae.

The trouble with rapidly diversifying Neotropical lineages: Can the current Pipunculidae classification be incorporated into new phylogenetic hypotheses?

Jeffrey H. Skevington[1], Christian Kehlmaier[2], Marc De Meyer[3], Jose A. Rafael[4], Scott Kelso[5]

[1]Agriculture and Agri-Food Canada, Canada, [2]Agriculture and Agri-Food Canada, Canada, [3]Agriculture and Agri-Food Canada, Canada, [4]Agriculture and Agri-Food Canada, Canada, [5]Agriculture and Agri-Food Canada, Canada

Pipunculidae are important parasitoids of leafhoppers and their relatives (Auchenorrhyncha). One bizarre, autapomorphic genus (Nephrocerus) was recently discovered to attack adult crane flies (Tipulidae). This deviation from the rest of the genus is also mirrored in unique morphology and has posed a considerable challenge for phylogenetic placement. We are now testing this and other previous hypotheses using 7528 base pairs of molecular data from the mitochondrial genes COI, 12s and cyt B and the nuclear genes AATS and CAD. In addition to the placement of enigmatic taxa like Nephrocerus, questions about the utility of some characters (particularly wing vein characters) have never been fully tested. To this end, we have sampled 159 ingroup taxa to more fully test the monophyly of and relationships between existing genera. The status of several sister taxa such as Jassidophaga/Verrallia, Microcephalops/Collinias,Cephalops/Cephalosphaera and Pipunculus/Parapipunculus are explored and the status of existing subgenera are also examined and re-interpreted. The biggest challenge within the Pipunculidae has been untangling the taxonomy of the huge tribe Eudorylini. Several genera of eudorlyines have been proposed with some expectation that the original genus Eudorylas is now a paraphyletic assemblage of leftover species. A morphologicaly analysis of this group was attempted recently but this is the first time that extensive sampling using multiple independent datasets have been brought to the question. Most genera have survived this test of their monophyly but some will clearly need to be redefined and at least two new genera will be proposed.

Explosive radiation of parasitoid flies: Phylogeny and evolution of tachinidae

John O. Stireman[1], Pierfilippo Cerretti[2], Dan J. Davis[3]

[1]Wright State University, U.S.A., [2]Sapienza University of Rome, Italy, [3]Wright State University, U.S.A.

The family Tachinidae is one of the most diverse families of Diptera and it is the most important group of insect parasitoids outside the Hymenoptera. All tachinids are endoparasitoids, attacking as a group at least 14 arthropod orders. They parasitize this diversity of hosts with a remarkable array of oviposition and reproductive strategies. Despite their diversity and importance, Tachinidae have been the subject of very little phylogenetic study. Composition of, and relationships among tribes and subfamilies are obscure and the family is among the most taxonomically difficult of Diptera. Here we report on some of the initial progress of our efforts to understand the phylogenetic relationships and evolution of this remarkable family using molecular and morphological data: 1. Large scale phylogenetic analyses indicate that the Tachinidae is one of the youngest and most rapidly diversifying families of Diptera. 2. Preliminary molecular phylogenetic analysis suggests that tachinids may have arisen from within a polyphyletic Calliphoridae. 3. Both morphological and molecular data support general groupings of subfamilies Dexiinae + Phasiinae and Tachininae + Exoristinae. 4. Of these subfamilies, only Exoristinae is well supported as monophyletic in both molecular and morphological analyses. 5. The evolution of egg type (ovipary, ovolarvipary) appears to be highly labile, and morphological data suggest that early hosts of tachinids were hemimetabolous with subsequent explosive diversification onto larval holometabolous hosts.

Mining Genbank to resolve Orthorrhapha: A supermatrix analysis of lower Brachycera

Michelle Trautwein[1], Keith Bayless[2], Shuan Winterton[3], Torsten Dikow[4], Brain Wiegmann[5], David Yeates[6]

[1]North Carolina Museum of Natural Sciences, U.S.A., [2]North Carolina Museum of Natural Sciences, U.S.A., [3]North Carolina Museum of Natural Sciences, U.S.A., [4]North Carolina Museum of Natural Sciences, U.S.A., [5]North Carolina Museum of Natural Sciences, U.S.A., [6]North Carolina Museum of Natural Sciences, U.S.A.

Fly evolution has undergone at least three rapid bursts of diversification, one occurring within the Lower Brachycera approximately 180 Ma. This region of the fly tree includes 23 families with a diversity of life histories: large flower visiting flies, blood feeders (Tabanidae, Athericidae, Rhagionidae), parasitoids (Bombyliidae, Acroceridae, Nemestrinidae) and predators (Asilidae). Though lower brachyceran families have traditionally been grouped together in Orthorrhapha, this group has widely been considered a paraphyly- lacking both morphological and molecular support. Recent large-scale molecular analyses of high-level fly phylogeny, however, found a monophyletic Orthorrhapha (excluding Empidoidea) to be well-supported. To test this unexpected result of orthorrhaphan monophyly, we have compiled a supermatrix of existing molecular markers from Genbank for a taxon dense sampling of lower brachycerans. This data set, including hundreds of taxa and up to 15 genes, is the largest compiled to date for the resolution of fly phylogeny.

Phylogenomic distribution and functions of DNA methylation in Insect genomes

Soojin Yi
Georgia Institute of Technology, U.S.A.

DNA methylation is an important epigenetic mechanism involved in regulatory and developmental processes. Recent genome projects have revealed that functional DNA methylation systems are widespread among invertebrates, in particular, insects. This observation raises several intriguing questions. Why are DNA methylation systems absent in some insect species, such as the model insect fruitfly? What does DNA methylation do in different species? What are the evolutionary implications of DNA methylation? Comparative analyses of DNA methylation have begun to address these questions. In this talk, I will first summarize results showing the variation in DNA methylation across insects (and more generally, invertebrates), and the multi-faceted functional role of DNA methylation. In addition, I will present results indicating significant role of DNA methylation in lineage-specific adaptive evolution. Together, these studies highlight the significance of DNA methylation in insect genome evolution. Moreover, insects are emerging as excellent model systems to investigate the functional roles and evolution of DNA methylation.

Phylogenomics and the evolution of insects - The 1KITE project

Bernhard Misof
on behalf of the 1KITE consortium, Germany

1KITE (1K Insect Transcriptome Evolution) is an international initiative that aims to study the transcriptomes of 1,000 insect species encompassing all recognized insect orders (www.1kite.org). We will address the phylogeny of insects by analyzing an unprecedented amount of nucleotide sequence data, allowing us to reconstruct the major character transformations and timing of diversifications in their evolution.. Scientists involved include experts in molecular biology, insect morphology, taxonomy, paleontology, embryology, bioinformatics, and scientific computing from eight nations (Australia, Austria, China, Germany, Japan, Mexico, New Zealand, and the US). 1KITE is divided into several subprojects focusing on specific phylogenetic groups, for example, apterygote hexapods, Odonata, Polyneoptera, Hymenoptera, Trichoptera, and Antliophora. Additionally, 1KITE includes the development of new software for data quality assessment, phylogenetic reconstruction, and molecular dating. Sequencing will be completed by the end of 2012. Preliminary analyses of the already available sequences show that the obtained data are of yet unparalleled size and quality. We were able to identify ~ 1000 1:1 orthologous genes for every transcriptome we sequenced and first results show that inferred trees have the potential to deliver a plausible backbone tree of insects with robust statistical support. The results can be expected to have an extraordinary and long-standing high impact on entomological and phylogenetic research.

Phylogenomic insights into the Cambrian explosion, the colonization of land and the evolution of flight in Arthropoda

Chris Wheat[1], Niklas Wahlberg[2]

[1]Stockholm University, Finland, [2]Stockholm University, Finland

The timing of the origin of arthropods in relation to the Cambrian explosion is still controversial, as are the timing of other arthropod macroevolutionary events such as the colonization of land and the evolution of flight. Here we assess the power of a phylogenomic approach to shed light on these major events in the evolutionary history of life on Earth. Analyzing a large phylogenomic dataset (122 taxa, 62 genes) with a Bayesian relaxed molecular clock, we simultaneously reconstructed the phylogenetic relationships and the absolute times of divergences among the arthropods. Simulations were used to test whether our analysis could distinguish between alternative Cambrian explosion scenarios with increasing levels of autocorrelated rate variation. Our analyses support previous phylogenomic hypotheses and simulations indicate a Precambrian origin of the arthropods. Our results provide insights into the three independent colonizations of land by arthropods and suggest that evolution of insect wings happened much earlier than the fossil record indicates, with flight evolving during a period of increasing oxygen levels and impressively large forests. These and other findings provide a foundation for macroevolutionary and comparative genomic study of Arthropoda.

Whole genomes help resolve the subordinal phylogeny of beetles

Duane D. McKenna
University of Memphis, U.S.A.

Beetles (order Coleoptera) comprise the largest order of animals. They are part of the food web in nearly every non-marine habitat and play numerous and important ecological roles. While molecular phylogenetic data have helped resolve some beetle relationships, others, particularly the interrelationships of the four beetle suborders (Adephaga, Archostemata, Myxophaga, and Polyphaga), remain uncertain. In this talk I will present results from my ongoing studies of beetle genomes, including what these data can tell us about interrelationships among the four suborders of beetles and relationships between beetles and their close relatives in other orders.

Resolving rapid radiations within Diptera: A phylogenomic approach

Michelle Trautwein[1], Brian Wiegmann[2]

[1]*North Carolina Museum of Natural Sciences, U.S.A.,* [2]*Dept. of Entomology, U.S.A.*

Recent efforts to recover the fly tree of life have greatly advanced our knowledge of fly phylogeny. Fly evolution has taken place in episodic bursts, including 3 ancient rapid radiations corresponding to: lower Diptera (mosquitoes; 220 Ma), lower Brachycera (horse flies;180 Ma), and Schizophora (Drosophila, house flies; 65 Ma). Ancient lineages that underwent rapid radiations, such as these, are often left unresolved by standard phylogenetic methods. Fly model organisms used across scientific disciplines all occur within these lineages and a fully resolved phylogenetic framework is needed for contextualizing the comparative biology of flies. As systematics transitions to the regular use of large-scale gene harvests, flies are an excellent phylogenomic study system because of the wealth of existing genomic data that has already been generated as a result of their role as important model organisms, disease vectors and agricultural pests. Now we aim to explore the utility of transcriptome data to further resolve these ancient rapid radiations in fly evolutionary history. Using new and existing data, we have identified thousands of orthologs shared across deep fly divergences, from Anopheles gambiae to Drosophila melanogaster. In comparison to targeted PCR, next-gen sequencing has more rapidly and affordably provided a wealth of genes that exhibit phylogenetic utility across flies.

The phasmatodean tree of life: Progress and enigmas

Sven Bradler[1], Thomas R. Buckley[2]

[1]University of Goettingen, Johann-Friedrich-Blumenbach-Institute for Zoology and Anthropology, Germany, [2]Landcare Research Auckland, New Zealand

The phasmatodeans or stick and leaf insects comprise more than 3000 described herbivorous arthropods distributed mainly in tropical and subtropical regions. Considered to be a mesodiverse insect order, the group has thus far received relatively little phylogenetic attention. According to recent morphological and molecular studies, many of the currently recognized suborders, families, subfamilies and tribes are not monophyletic, with few exceptions. For instance, the Necrosciinae, the most species-rich traditional subfamily of stick insects, appears to be broadly monophyletic, with only a few species 'misplaced'. In contrast, the tree lobsters or Eurycanthinae, which comprise a small number of specialized ground-dwellers on Pacific islands, are polyphyletic, exhibiting a high degree of convergent evolution. In general, molecular analyses have demonstrated that phylogeny correlates better with geographic distribution than with morphological similarities. Since stick insects possess only limited dispersal capabilities, they are ideal model organisms for biogeographic research. Numerous previously unexpected lineages of stick insects have been recovered now. However, the relationships among these clades are contentious. For instance, the leaf insects (Phylliinae) frequently change their supposed phylogenetic position among Phasmatodea across different data matrices and methodologies. This problem might reflect a rapid ancient radiation of stick insects that gave rise to the diversity of extant forms and highlights the need to explore further sources of evidence.

Paleobiology of fossil stick- and leaf-insects

Sonja Wedmann[1], Sven Bradler[2]
[1]*Senckenberg Research Institute, Germany,* [2]*University of Goettingen, Germany*

Among insects, various defensive strategies have been developed to protect them against predators. Defensive behaviours can be divided in primary and secondary defenses. Primary defenses operate regardless of the presence of a predator and thus decrease the chance of encounter with an predator, secondary defenses operate when a predator is present and increase the chances of survival of the prey. The main primary defense mechanism is crypsis. The evolution of the elaborate morphological adaptations of phasmids to the mimicking of plants is largely still unclear, but some fossils allow further insights. We give an overview of fossils which allow conclusions on the course of evolution of plant mimicking. The preserved morphological structures also allow inferences on the former behaviour of the phasmids. For example, Eocene fossils from Baltic amber (Russia) and from the fossil site Grube Messel (Germany) show basally curved fore femora. These curved femora enclose the head in the typically resting position of stick and leaf mimics, which is adopted during catalepsy or adaptive stillness at daylight. The Eocene Eophyllium messelense indicated that leaf insects descended from stick insect ancestry and illuminates the evolution of leaf mimicry. As a secondary defense mechanism, numerous extant stick insects have an autotomy mechanism that severs the leg at the femoral-trochanter joint. An Eocene stick insect from Grube Messel indicates that this behaviour had already evolved in the Eocene. Appendotomy and the capability of regenerating legs might have even influenced multiple losses of wings.

Homologies in stick-insect wing venation and taxonomic implications

Olivier Bethoux
France

Conjectures of topographic homologies in stick-insects wing venation pattern have been seldom investigated, and results are contradictory. The position of the group within insect phylogeny is a matter of debate, although nested as sister-group of orthopterans (grasshoppers, crickets and their kin) has been historically favoured. Concurrently, identification of Mesozoic (Palaeozoic?) relatives is not evident. In order to address these issues a collection of extant stick-insect wings was prepared and a comparative analysis of wing venation pattern was undertaken. Successive vein fusions are documented based on transformation series across species, and intra-specific and intra-individual variability. Cases of vein loss and vein translocation are also documented. It is argued that stick-insect hind wings have a wing venation pattern diagnostic of orthopterans, in particular a branched CuP. Putative fossil representatives are reconsidered, and closer relationships with Caelifera are hypothesized.

Flight in stick insects: Biomechanics and implications for ecology and evolution

Yu Zeng[1], Robert Dudley[2]

[1]University of California at Berkeley, U.S.A., [2]University of California at Berkeley, U.S.A.

Stick insects exhibit a wide spectrum of wing size variation, which potentially implies differences in function, ecology and evolutionary history. Here we investigate the functionality of flight in stick insects using integrative approaches. First, quantitative measurements of the wing venation and membrane morphology in wings of different sizes showed a continuous structural reduction and simplification along the size gradient. Second, assisted with high-speed filming and biomechanical analysis, we revealed diverse flight performances associated with different wings, from full flapping capacity to gliding or parachuting with reduced wings. Species with better developed wings generally show greater flight capabilities, and short-wing species show distinctive features in wing flapping kinematics and aerodynamics. Comparison among different flight modes suggests a transition in the functionality of flight along with the transition in wing size. The variation of flight capability in stick insects may be ecologically related with environmental gradients. Understanding the adaptive significance of various wing designs in stick insects may help to explain the evolutionary transitions between flightless and volant forms.

Evolution and systematic position of Phasmatodea - A morphological approach

Benjamin Wipfler[1], Rolf G Beutel[2]

[1]*University Jena, Germany,* [2]*University Jena, Germany*

Phasmatodea (walking leaves, stick and leaf insects) comprise around 3000 species, most of them occurring in the tropical regions. Along with Blattodea, Orthoptera, Dermaptera and some other groups they belong to the lower neopteran insects (Polyneoptera), which diversified in a very short time span in the late Carboniferous some 300 million years ago. This rapid radiation is reflected by the still unresolved relationships between the modern lower neopteran orders. Phasmatodeans have long been considered as closest relatives of Orthoptera (grasshoppers, crickets and katydids) or even as a subordinate group. However, several recent morphological studies and also analyses of molecular data indicate a sistergroup relationship between Phasmatodea and the cryptic Embioptera (webspinners). Potential synapomorphies include eggs with an operculum and an internal micropylar plate and several derived muscular features of the head.

New insights into the evolution of sperm structure in stick and leaf insects

Marco Gottardo[1], Romano Dallai[2]
[1]University of Siena, Italy, [2]University of Siena, Italy

The sperm structure of representatives of Phasmatodea was studied by light microscopy, and scanning and transmission electron microscopy. In Timema, a putative basal phasmatodean lineage, spermatozoa are short flagellate cells about 55-60 µm in length. They are characterized by a three-layered acrosomal complex. The distinctive bell-shaped morphology of the acrosome vesicle is likely an autapomorphic trait of Timema. The flagellum has a 9 + 9 + 2 axonemal pattern, two accessory bodies, two membranous sacs, and two elongated mitochondrial derivatives. Results support the hypothesis of a monophyletic Phasmatodea, comprising Timema + Euphasmatodea. The presence of 17 protofilaments in the wall of accessory microtubules, and the laminar configuration of the flagellum are potential apomorphic groundplan features of the order. Within Phasmatodea, a key evolutionary divergence was from the conventional insect spermiogenesis and sperm structure of Timema, to the unusual spermiogenetic process and peculiar sperm structure of Euphasmatodea. As a consequence, Timema retains more sperm chatacter states found in the polyneopteran ground pattern, and is mostly characterized by plesiomorphic traits. Conversely, Euphasmatodea have evolved several derived sperm features. Putative autapomorphies of Euphasmatodea include the loss of mitochondria and membranous sacs, and the presence of two strongly expanded accessory bodies. Within Euphasmatodea, spermatozoa display major differences in cell-size, morphology of accessory bodies, and structure of the acrosomal complex.

Systematics, Phylogeny and Zoogeography

Affinity of phasmatodea: Embryological evidence

Toshiki Uchifune[1], Yoshie Uchifune[2], Yuta Mashimo[3], Ryuichiro Machida[4]

[1]Yokosuka City Museum, Japan, [2]Japan Agency for Marine-Earth Science and Technology, Japan, [3]University of Tsukuba, Japan, [4]University of Tsukuba, Japan

Embryogenesis of Phasmatodea is characterized by mesoderm segregation of fault type, development of short germ band type, and embryo's localization on egg surface. The former two are the groundplan of Polyneoptera, and the third one, which is shared by some groups of Polyneoptera, cannot develop a plausible phylogenetic discussion. Hereat, egg features deserve a special mention. Phasmatodean eggs are characterized by an operculum at anterior egg pole, a micropyle at ventral egg side, and a polar mound at posterior egg pole. These features are unique, but only Embioptera bear a set of these features. They may be regarded as synapomorphies of Phasmatodea and Embioptera, and Eukinolabia is supported. Although the micropyle of Eukinolabia has been understood to be single, Timematodea were recently revealed to have a pair of micropyles and at least some phasmatodean forms to possess the micropyles adjacently paired. The embiopteran egg has a single micropylar tube, but its canal is flattened, often showing dumbbell-shape in cross section, as if paired micropyles were fused into one. Thus, the micropyles of Eukinolabia may be asserted to be paired as groundplan. Paired micropyles are peculiar in Polyneoptera but only found in Zoraptera. The affinity between Eukinolabia and Zoraptera is suggested. Hereat, recent information from spermatozoa may be interesting (Dallai et al., 2011): Phasmatodea and Zoraptera share the number of protofilaments of accessory tubules "17" which is singular among Polyneoptera; Eukinolabia and Zoraptera share a peculiar feature concerning the centriole adjunct. Furthermore, Embioptera and Zoraptera share an extraordinarily elongated egg tooth.

Molecular phylogeny of stick insects based on mitochondrial genome

Natuo Komoto[1], Kenji Yukuhiro[2], Shuichiro Tomita[3]

[1]National Institute of Agrobiological Sciences, Japan, Japan, [2]National Institute of Agrobiological Sciences, Japan, Japan, [3]National Institute of Agrobiological Sciences, Japan, Japan

Stick and leaf insects are famous for the extreme adaptation of crypsis, which can lead to morphological convergence making it difficult to infer phylogenetic relationships. In order to circumvent the morphological constraints, we present molecular phylogeny of Phasmatodea depending on mitochondrial DNA (mtDNA).There are advantages of mtDNAs for phylogenetic analyses, such as the absence of recombination, introns, and paralogs. PCR-based cloning of mtDNA is also helpful to obtain relatively large data sets. We have sequenced the mtDNAs of more than 20 phasmatodean species. All of the mtDNAs share the same gene arrangement as putative ancestral Pancrustacea mtDNA. The phylogenetic relationships inferred by the mtDNA sequences resulted in disagreement with conventional taxonomy based on morphology. For example, the molecular phylogeny did not support the monophyly of Areolatae or Anareolatae, two major groups of Phasmatodea. There are discrepancies also at the subfamily level; for example, Neohirasea, a member of Lonchodinae, was grouped with species of Necrosciinae in our analyses. The position of Timema is controversial. It has long been regarded as a basal taxon of stick insects, included in Areolatae. Our analyses showed that Timema is distantly related to the other phasmatodean species, suggesting that it will be necessary to revise the phylogenetic position of Phasmatodea in Polyneoptera.

Phylogeny and genome evolution in the New Zealand stick insects (Phasmatodea)

Thomas Buckley[1], Luke Dunning[2], Alice Dennis[3], Shelley Myers[4], Geoffrey Thomson[5], Sven Bradler[6]
[1]Landcare Research, New Zealand, [2]Landcare Research, New Zealand, [3]Landcare Research, New Zealand, [4]Landcare Research, New Zealand, [5]Landcare Research, New Zealand, [6]Georg-August-Universitat, Germany

The New Zealand stick insect fauna contains 10 genera and 23 described species, in addition to several undescribed species. We have reconstructed a phylogeny from multiple nuclear and mitochondrial genes to determine the biogeographic origins and diversification of the New Zealand stick insects. Two independent lineages were recovered both with sister taxa in New Caledonia and both of similar age. One of these lineages is monotypic and the other contains the remaining 22 species. Phylogenetic relationships among the individual gene trees vary and we discuss the significance of this incongruence and resolution of a species phylogeny. The New Zealand stick insects descended from subtropical and tropical ancestors yet now inhabit temperate environments. Two genera have species that are alpine obligates or found in lowland and alpine habitats. We have also performed analysis of transcriptome data to reveal genes that are involved temperature stress response and under selection. These latter genes are candidates for involvement in adaptation to these new environments and include genes involved in energy metabolism.

How clasper morphology relates to genetic and behavioural isolation in the New Zealand stick insect genus *Clitarchus*

Shelley Susan Myers[1], Alice Dennis[2], Gregory I. Holwell[3], Thomas R. Buckley[4]

[1]Landcare research, University of Auckland, New Zealand, [2]Landcare Research, New Zealand, [3]University of Auckland, New Zealand, [4]Landcare research, New Zealand

A hybrid zone is the geographic area where two species meet and form offspring. It is common for the offspring of hybridising species to have reduced fitness. The theory of reinforcement predicts that prezygotic barriers will evolve between hybridising groups and there will be selection against hybridisation. In the Far North of New Zealand, the widely-distributed stick insect species C. hookeri is replaced by an ecologically similar and undescribed species of Clitarchus. These species are differentiated on the basis of male terminalia (specifically the claspers), egg morphology and mitochondrial DNA. Populations sampled between the two species show intermediate morphology. The aim of this research project is to describe the level of isolation between species of Clitarchus using interdisplinary techniques including behavioural studies, genetics and morphology. Genetic divergence and gene flow is being measured using SNP data obtained from 454 genomic reduction sequencing. Three dimensional morphometrics accurately describes differences in intra and inter-specific clasper shape. These quantitative approaches are being combined with mating experiments to provide a basis for addressing the following questions: does variation in morphology correspond to differences in mating behaviour and does morphological variation correlate with reproductive isolation?

The stick insects of Madagascar: Ancient lineages or recent adaptive radiation?

Julia Goldberg[1], Sven Bradler[2]
[1]University of Goettingen, Germany, [2]University of Goettingen, Germany

Madagascar is one of our planet's leading biodiversity hotspots exhibiting an extraordinarily distinct and diverse biota. Many elements of its fauna are still poorly documented and remain largely unexplored. One example is the Malagasy stick insects (Phasmatodea) whose evolutionary history is entirely obscure. Stick insects are large terrestrial arthropods with limited direct-dispersal abilities, forming at least four distinct taxonomic groups on Madagascar, i.e., endemic families and subfamilies. Their phylogenetic affinities to continental lineages are completely unresolved. We present informative sets of molecular and morphometric data to investigate the origin and evolution of Malagasy stick insect lineages. Analysing a representative taxon sampling we demonstrate that the stick insects of Madagascar are more closely related to each other and much younger than previously suggested in traditional classifications, representing a classical example of adaptive radiation in geographic isolation. The application of a comparative morphospace analysis to the obtained phylogeny additionally provides an opportunity to compare unrelated and geographically distant radiations among phasmatodeans, for instance those of Madagascar compared to a diverse lineage of Australasian stick insects (Lanceocercata). Thereby, we detect an impressive degree of convergence between these otherwise distinct communities.

Bio[phylo]geo[eco]graphy: The multidisciplinary nature of plant and animal geography

Malte Ebach
University of New South Wales, Australia

21st century biogeography is in a state of denial. Biologists believe that biogeography is a single scientific field with a single goal and common history - a field that can somehow be unified methodologically. Ecologists, taxonomists, molecular systematists, bacteriologists, astrobiologists, geographers, conservation biologists and palaeontologists all do "biogeography" of one kind or another, but each ask very different and often conflicting questions. To an outsider, it is hardly surprising to discover that biogeography has multiple origins that ask separate questions and do different things. Then why do some biogeographers believe that a highly diverse field can be unified, especially by a single methodology? The short answer is a lack of integration and interdisciplinary projects, virtually no exposure to biogeographical theory and history. Most important is the belief that a single term, "biogeography", originally undefined, is enough to encapsulate various disciplines, aims and practices as a single field. Rather than talk of unification, biogeographers should look to their strengths and embrace a multidisciplinary field that has a enormous potential. This talks hopes to untangle these beliefs and reveal the exciting problems that the multidisciplinary field of biogeography has still to answer.

Biogeographical units: Kinds of boundaries or individual wholes?

Eduardo A. B. Almeida[1], Renato S. Capellari[2], Silvio S. Nihei[3]

[1]Universidade de Sao Paulo (USP), Brazil, [2]Universidade de Sao Paulo (USP), Brazil, [3]Universidade de Sao Paulo (IB-USP), Brazil

The role played by areas of endemism in the study of biogeography is analogous to that of species in the context taxonomy: areas of endemism (AE) can be viewed as the fundamental units of biogeographical research. Despite various criticisms made regarding the usage of AE, delimitation of these units has proved to at least have some empirical utility. Because of that, we can think of AE as an imperfect concept, which can partly accommodate our knowledge and predictions, but that often fails to express our hypotheses about spatial evolution. Here, we promote the notion that the vicariant events are the real focus and the genuine units of biogeography, in agreement with Hovenkamp's proposals. Shifting from an AE-based approach to this alternative strategy requires attention to be directed to the boundary (or part of the boundary), instead of the area itself. These boundaries, namely 'hypotheses of vicariant boundary' (VB), can be construed as fuzzy elements of the world conveying historical information due to vicariance, best thought of as natural kinds concepts. No necessary or sufficient properties need to be ascribed to these kinds, because unique histories may have molded these units differently over time, generating distinct homeostatic property clusters in each situation. The nomological commonness among all cases of VB's, i.e., generational vicariant processes, makes these kinds relevant for the study of historical biogeography as the fundamental units of this field of investigation. The importance of VB-based biogeography will be exemplified with examples from previously conducted biogeographical research with insects.

Many oriental regions

Dalton de Souza Amorim
Universidade de Sao Paulo, Brazil

Biogeography uses areas as units to produce hierarchical systems. The nature of space as biogeographical units is intrinsically different from terminals in other systems, as species in phylogenies or individuals in genealogies. Horizontal transfer is much more common in biogeography than in other systems, cases in which isolated fauna and flora begin to co-exist with new elements, so that the "age" of taxa in an area may differ. Most methods use the same term for all taxa occupying the same area. In logics, paraconsistency is the property of two equally denoted items being different, implying that logical consequence is not explosive, i.e., {A , ¬A} ? B. In biogeography this concept is applicable in the sense that the same area may have elements connected to different areas without denoting contradiction. Coexistence of different faunas and faunas is recognized in texts, but numerical analyses usually lack tools to discern biogeographical layers, thus avoiding unnecessary conflict between data. The inability of most methods to deal with "contradictory signals" results in loss or distortion of information. The Oriental diversity of Diptera is analyzed and its different layers are recognized. It includes elements: (1) of southeast Palearctic origin (i.e., connected to China or other Palearctic areas); (2) of Australian origin (with close relatives, e.g., in tropical Papua-New Guinea); (3) of tropical Gondwanan origin (with its relatives mainly in Africa); and (4) of tropical Laurasian origin (with most relatives extinct, and remnants present, e.g., in tropical Nearctic areas). Examples are given and implications are considered.

The wings of butterflies: Active dispersal through time or passive movements?

Mikko Niklas Wahlberg
University of Turku, Finland

Recent advances in using molecular data, calibrated with fossil evidence, to estimate the times of divergence of lineages in almost any group of organisms has brought fresh understanding to where various organisms have originated and how they got to where they are today. I will review the state of knowledge in butterflies, a group that has long been speculated to have been influenced by the break up of Gondwana. Our work on the family Nymphalidae shows that most lineages are too young for vicariance to have played a major role in explaining the current distributions of species. In contrast, it is very clear that butterflies have actively dispersed, although it is apparent that successful colonizations of new areas happens rarely enough that clear phylogenetic patterns are retained.

The fossils within: Use of nuclear mitochondrial pseudogenes to understand historical biogeography

Hojun Song
University of Central Florida, U.S.A.

Inadvertent coamplification of nuclear mitochondrial pseudogenes (numts) is a serious problem in mitochondrial systematics, but numts can also be a valuable source of information because they represent ancient forms of mtDNA. In this presentation, I introduce a conceptual framework of numt accumulation, which states that in a given species there can be two types of numts, synaponumts and autaponumts, resulting from integration occurring respectively before and after a speciation event. In a given clade, a species that diverged early can only have its own autaponumts as well as synaponumts that were already present in the genome of the last common ancestor. A species that diverged more recently may, however, have many different synaponumts integrated at each different divergence as well as its own autaponumts. Therefore, it is possible to decipher the evolutionary history of a species based on the phylogenetic distribution of numts in a simultaneous analysis of numts and extant mtDNA. I empirically test this idea in the context of addressing a controversial question regarding the biogeography of the grasshopper genus Schistocerca Stal, based on numts of cytochrome c oxidase subunit I (COI) gene. I find that the empirical data can be adequately explained by the conceptual framework and that the phylogenetic distribution of COI numts reveals intricate evolutionary histories about past speciation events that are otherwise difficult to detect using conventional markers. This study demonstrates that numts provide interesting and powerful phylogenetic signal, much more than what extant mtDNA or nuclear gene sequences might be able to provide.

The interface of biogeography and phylogeography in dune restricted insects in North America

Matthew H. Van Dam
UC Berkeley, U.S.A.

The sand dunes of Southwestern North America are a continental archipelago. Using probabilistic methods to explicitly test not only the pattern but also the divergence dates among taxa is a marked departure from previous parsimony based methods. I hope to synthesize the results from multiple unrelated taxa to test alternative dispersal patterns in this island system. I will also be addressing questions of species delimitation and how that plays an integral part in how we define biogeography and phylogeography.

A history of bioregionalisation in Australia

Malte C. Ebach
University of New South Wales, Australia

The development of Australian biogeographical regionalisation since 1805 has been driven by colonial 19th-century exploration and by the late 20th-century biodiversity crisis. The intervening years reduced existing large scale regionalisations into smaller taxon specific areas of vegetation or endemism. However, large scale biotic biogeographical regionalisation were rediscovered during multi-disciplinary meetings and conferences, sparking short-term revivals, which have ended in constant revisions at smaller and smaller taxonomic scales. In 1995 and 1998, the Interim Biogeographic Regionalisation for Australia and the Integrated Marine and Coastal Regionalisation of Australia, Australian Commonwealth funded initiatives in order to "identify appropriate regionalisations to assess and plan for the protection of biological diversity", have respectively replaced 190 years of Australian biogeographical regionalisation. This talk looks at the rise and slow demise of biogeographical regionalisation in Australia in light of a fractured taxonomic biogeographical community.

Global biogeographic patterns of grassland Auchenorrhyncha

Therese Anne Catanach[1], Chris H. Dietrich[2]
[1]*University of Illinois, U.S.A.*, [2]*University of Illinois, U.S.A.*

Patterns of grassland biogeography were inferred using 3 tribes of leafhoppers (Deltocephalini, Paralimnini, and Hecalini) and a family of planthoppers (Caliscelidae). Previous biogeographic study of this biome has been based on ungulates or other groups which have either limited distributions, or a small number of taxa. Although little is known about the relationships between closely related lineages of insects occurring on the various grasslands of the world available studies suggest a much more complex biogeographic history than that elucidated by ungulates. The lineages selected for this study however are hyperdiverse and globally distributed, although genera and species have localized distributions, allowing for fine scale patterns also to be drawn. In addition to biogeographic patterns we tested theories regarding host specialization, and comparing distributional relatedness patterns to grasses. Presented here are phylogenetic analysis of each lineage based on 3 genes, and a biogeographic analysis for each lineage. Preliminary phylogenetic results based on DNA sequence data indicate that biogeographic patterns of grassland leafhoppers are more complex than those of previously studied groups of grassland organisms, with multiple invasions of various grassland regions within each lineage. Along with phylogenetic and biogeographic results this study has conservation implications. Grasslands are rapidly being destroyed and identifications of regions possessing many unique lineages would allow these regions to be targeted for further protection.

Historical biogeography of Australian true bugs

Gerasimos Cassis
University of New South Wales, Australia

Land bug (Insecta: Hemiptera: Geocorisae) diversification is inexorably linked to their interactions with seed plants. Our understanding of how these interactions impact on the distribution of these taxa is cursory. Australian land bugs are highly diverse, and a plethora of new studies enables their use as a model taxon for testing current theories of area relationships in Australia. Phylogenies and taxon areagrams are presented for monophyletic groups from the families Miridae, Tingidae, Rhyparochromidae, Piesmatidae and Coreidae. These demonstrate a major split between areas defined by the Great Dividing Range from those of arid and southwest Western Australia. These results are contrasted against independent studies for vertebrates and flowering plants, and a 'total evidence' areagram is presented for land bugs, vertebrates and flowering plants.

Austral biogeography: Goodbye Gondwana and the Moa buoyancy hypothesis

David Yeates
CSIRO Ecosystem Sciences, Australia

Our understanding of the biogeography of the southern end of the world has been revolutionized in recent years. The comfortable assumption that austral distributions can be explained by Gondwanan ancestry followed by vicariance has been overturned by evidence from studies estimating divergence times of key austral taxa using molecular data. A number of iconic gondwanan groups contain internal nodes that are too young to be explained by gondwanan vicariance, and suggest that long distance over-ocean dispersal has been an important process in shaping austral distributions. Our knowledge of these distributions and the processes that shape them will improve as we gain further insights into the distribution of extant and extinct austral lineages and improve divergence time estimation methods. A number of processes are likely to have affected the distribution of each austral lineage, and ecological factors will influence the probability of these processes. We discuss these issues using recent evidence from Diptera and Mecoptera.

Local variation, species, and biogeography of New Zealand beetles

Rich Leschen[1], Thomas Buckley[2], Katie Marske[3], Nathan Lord[4]

[1]Landcare Research, New Zealand, [2]Landcare Research, New Zealand, [3]University of Copenhagen, Denmark, [4]University of New Mexico, U.S.A.

New Zealand is a well-known, model location for understanding biogeographic patterns and a review of the problems during on-going work to explain glacial refugia, endemism, island biogeogeography and species/population assembly is presented. One of the major challenges is the poor taxonomy of microcoleoptera which we have been rectified by 1) revising the species prior to genetic studies or 2) revising focal groups as genetic studies ensue. This has proven effective, but for hyperdiverse groups like Zopheridae (the 4th largest group of beetles in NZ with over 200 species), multiple new species and non-monophyletic genera have been encountered, which cannot be revised in a short time frame. Nevertheless, our studies have shown that offshore islands contain a mixture of old and new lineages, deep haplotype diversity on the mainland corresponds to glacial refugia and/or areas of high species richness, and biotic gaps are the result of glaciation extirpation and unequal rates of recolonization among species. Studies are now underway to investigate unusual genetic patterns that appear to be associated with living in the soil, aptery, and alpine distributions.

Evolutionary and biogeographic patterns in African and Madagascan dung beetles (Scarabaeidae: Scarabaeinae)

Catherine Lynne Sole[1], Clarke Henry Scholtz[2]
[1]University of Pretoria, South Africa, [2]University of Pretoria, South Africa

Three hypotheses are proposed and discussed: (i) Dung beetles evolved in Africa (ii) Dispersal into new areas as opposed to vicariance and (iii) Fungus as the ancestral food type with subsequent radiation onto vacant ecological space. Africa not only has some of the world's most spectacular mammals but also the richest dung beetle diversity. Although dung beetles have worldwide distribution, recent biogeographic and phylogenetic evidence supports the hypothesis that nine of the 11 tribes are unequivocally African in origin. A group once thought to have radiated either prior to continental fragmentation and possibly in response to the availability of dinosaur dung has been shown to be capable of widespread dispersal. The present-day genera, the endemic Helictopleurus and the three species of Scarabaeus, on Madagascar are comprised of lineages based on Miocene dispersers from Africa as opposed to evolving in situ after an ancient vicariant event. Their dispersal ability is substantiated by that of the genus Nesosisyphus, which is endemic to the relatively young (8 MYA) oceanic volcanic island of Mauritius thousands of kilometres from either Africa or India as potential sources of origin. Three genera from the earliest diverging lineages, Coptorhina, Delopleurus, and Frankenbergerius, are known to breed in and feed on fungus supporting the hypothesis of an ancestral feeding pattern on fungus with the change to mammalian dung being precipitated by both an increase in the amount of mammalian dung during the Tertiary and the ease of the switch between fungal microbes and those of dung.

Morphology and biogeographic patterns of ground beetles in Far East countries (Coleoptera, Carabidae, Pterostichinae)

Jong Kyun Park
Kyungpook National University, Republic of Korea

Pterostichids species are largest sized group in ground beetles, they usually live in deep forest area and feed on worms or decayed organism. Among them, species of subgenus Nialoe of Pterostichus have differential distribution, they occurred only far eastern countries, Korea, Japan and China, all known species are endemic without overlapping with other countries. The subgenus Nialoe species are distinct sexual heteromorphy in last segment of abdomen. Special shape of projection in last sternum of abdomen is important external key for classification. In this subgenus, totally 51 species are known in the world (Bousquet, 2003). 41 species are distributed in Japan, and then Korea and china are recorded 9 and 1 species respectively. These species have not hind wing, so they must move only working, it is the one of the reasons of regional isolation and also is caused to raise the species diversity. Korea, Japan and China located closely, but they have quite different specific characteristics in protuberance's shapes of last abdominal segment in male. Comparative studies on subgenus Nialoe of Pterostichus by geography, morphology are provided.

Large-scale biogeography of Carabid beetles using phylobetadiversity methods

Kipling Will
University of California, U.S.A.

Phylobetadiversity measures hold promise as an alternative means to view large-scale biogeographic patterns with a focus on the assembly of a fauna and its phylogenetic composition. Although these methods are now being used extensively in ecological studies and for relatively recent patterns, they have not been applied to geologically old patterns at the level of continents or globally. I will present results from an exploration of these methods applied to Carabid beetles with a Gondwanan distribution and across the islands of the Pacific. The study will be based on approximately 3000 species and a 500+ taxon phylogeny that will be the basis for the user compromise tree produced by Phylomatic. NRI and NTI measures will be used to look for the phylogenetic signature in Carabidae (Coleoptera) of "oceanic" vs. continents and "continental fragment" islands.

Biogeographic patterns of Pacific Orthotylinae

Michael Peter Elias
University of New South Wales, Australia

Biogeographic patterns in the southwest Pacific have long held interest for biologists, with a variety of theories proposed to explain taxic distribution and relationship of areas. The plant bug tribe Orthotylini (Insecta: Hemiptera: Miridae) comprises a high diversity of genera and species in this region of the Pacific, many of which are undescribed. Several of these taxa display characteristics, which are atypical of any of the suprageneric groupings of the Orthotylinae. We report on systematic revisions of several of these genera and analyse patterns of distribution in the southwest Pacific. These patterns are compared with current theories of area relationships for other components of the biota of the southwest Pacific.

Alticinae (Coleoptera: Chrysomelidae) diversity in Oaxaca, Mexico: A preliminary study

David George Furth
Smithsonian Institution, U.S.A.

These results are part of a preliminary study of the insect diversity of the southern Mexican state of Oaxaca. Presented are the results from fieldwork carried out in August-September 2010. Approximately 48 species in 25 genera of Alticinae (Coleoptera: Chrysomelidae) were collected. This is added to previously recorded data from the literature as well as records from several North American collection holdings.

Phylogeny and evolution of Chrysomeloidea (leaf beetles and long-horned beetles)

Duane D. McKenna[1], Brian D. Farrell[2]
[1]University of Memphis, U.S.A., [2]Harvard University, U.S.A.

The sister superfamilies Chrysomeloidea (leaf beetles and long-horned beetles) and Curculionoidea (weevils) together form the uniquely diverse clade Phytophaga. While the reciprocal monophyly of Chrysomeloidea and Curculionoidea is relatively well-established, many questions remain about the internal phylogenies of these superfamilies, and about timing and patterns of taxonomic and ecological diversification across Phytophaga. In this talk I will review the current status of our understanding of the phylogeny and evolution of Phytophaga with a special focus on the superfamily Chrysomeloidea. Additionally, I will share preliminary results from ongoing studies designed to clarify family- and subfamily-level relationships in Chrysomeloidea and timing and patterns of chrysomeloid diversification. Particular emphasis will be placed on the family Cerambycidae and the early-divergent subfamilies of Chrysomelidae.

Secondary sexual characters in the Diabroticites (Chrysomelidae, Galerucinae)

Laura Rocha Prado
Museu de Zoologia da Universidade de Sao Paulo, Brazil

Secondary sexual characters (SSCs) result from structures that are modified in one of the genders, usually the male, considered to participate in non-sexual contact during copulatory behaviour. SSCs are regarded as both products of sexual selection, and a testimonial of the biodiversity. The relevance of SSCs throughout the history of chrysomelid beetles is remarkable. Among the species included in the subfamily Galerucinae senso strictu, the diversity of such characters is particularly impressive, with modifications reported as occurring in every tagma. The great specificity of these variations is often useful in the identification of male specimens at generic level, and the galerucine beetles of the section Diabroticites (tribe Luperini, subtribe Diabroticina) are no exception. From a total of 17 genera included in this group, 10 were first described based on at least one SSC, mostly found in the head. A review of the main SSCs reported in the Diabroticites is provided, with a discussion of its relevance for taxonomy. The evolutionary hypotheses stated for such a display of variation and its influence in the reconstruction of the phylogenetic history of this group are also presented.

Notes on the ecology of rolled leaf hispines (Chrysomelidae: Hispinae) at La Gamba (Costa Rica)

Michael Schmitt
Ernst-Moritz-Arndt-Universitat Greifswald, Germany

Michael Schmitt & Meike Frank Allgemeine & Systematische Zoologie, Ernst-Moritz-Arndt-Universitaet, D-17489 Greifswald, Germany, michael.schmitt@uni-greifswald.de During a field study at La Gamba (Golfito region, Costa Rica), a total of 322 adult hispine beetles of the genera Cephaloleia and Chelobasis have been found in rolled leaves of plants of 16 species of the order Zingiberales (families Costaceae, Heliconiaceae, Maranthaceae, and Zingioberaceae). Of these beetles, Cephaloleia belti was recorded from 11 host plant species, C. dilaticollis from 7, C. distincta from 6, Chelobasis bicolor from 4, C. championi from 3, and Chelobasis perplexa, C. histrionica, C. instabilis and C. trivittata from 2 each. Of the plant species, Heliconia imbricata had 7 beetle species in its leaf rolls, H. longiflora 6, H. rostrata and H. latispatha both had 5, Alpinia purpurata, Calathea lasiohylla, H. wagneri, H. stricta, and Calathea platystacha harboured 2 beetle species each, while on Costus pulverulentus, Calathea lutea, Calathea insignis, Costus barbatus, H. densiflora, H. vaginalis, and H. danielsana only hispines of one species were found. Cephaloleia belti occurred together with beetles of five other hispine species, whereas Cephaloleia trivittata never shared a leaf roll with another hispine species. The remaining beetle species aggregated with one to four other hispines. Adults of C. dilaticollis and C. championi were frequently seen to co-occur with the carabid Calophaena ligata in the same leaf roll without any sign of interspecific aggression. As they did not even interact in a perceivable manner, the nature of this association remains enigmatic.

Biology of *Caryedon prosopidis* Arora (Coleopteran: Bruchidae) on acacia Arabica(Lam.) willd – A new host record

Desh Raj Thakur
Himachal Pradesh University, India

Bruchide constitutes a homogeneous family of seed beetles that attack seeds of wild and cultivated leguminous plants worldwide. Most economic species of bruchids belongs to six key genera viz. Acanthoscelides Bruchus Bruchidius, Callosobruchus, Caryedon and Zabrotes. Species belonging to Bruchidius and Caryedon are generally field bruchids that attack the seeds and pods of wild leguminous plants. Caryedon prosopidis Arora (Coleoptera: Bruchidae) has been reported initially from Prosopis juliflora (Swartz) DC but present findings have unveiled its infestations from pods and seeds of Acacia arabica (Lam.) Willd. Gravid female laid 19.5 + 1.4 eggs during dusk and down and incubation period lasted for 8.5 + 1.1 days. All larval instar were voracious feeders and their development was completed inside the host seed. Larval duration lasted for 29.7 + 2.2 days and last instar larva emerged out of seed by cutting a hole to pupate outside. Larvae undergo four moults before pupation and pupal stages lasted for 32.7 + 1.04 days inside the cocoon. Adult insects emerged out in 63.6 + 3.4 days after cutting a circular lid at one end of the cocoon and longevity of insect lasted for 30.0 + 1.67 day during favourable period.

Discerning pattern in the connection of Cassidinae (Coleoptera, Chrysomelidae) and host plants

Donald Windsor
Smithsonian Institution, Panama

Many of us record "biological data" such as host plant identity when we make collections. But what do we to do with this information? The construction of trophic webs is one option. Their construction distills a great deal of complexity into metrics and graphics which facilitate comparisons among taxa, guilds and communities. We present results from studies of Cassidinae leaf scrapers and leaf miners in Panama, Bolivia and elsewhere which reveal significant differences in the way some taxa within Chrysomelidae are connected to host plants.

Evolutionary history of gall-forming aphids of the tribe Eriosomatini (Aphididae: Eriosomatinae)

Masakazu Sano[1], Shin-ichi Akimoto[2]
[1]Hokkaido University, Japan, [2]Hokkaido University, Japan

Reconstruction of evolutionary transitions in insect-host associations on the inferred phylogenies is crucial for understanding the evolutionary histories of the insect group. We inferred phylogenetic relationships of the aphid tribe Eriosomatini, gall-formers on the ulmacean genera Ulmus and Zelkova, based on morphological characters. The evolution of the eriosomatine aphids is discussed in relation to the reconstructed aphid-host associations and information about host-plant phylogenies and fossil records. Phylogenetic analysis with equal character weighting led to hundreds of most-parsimonious trees, but the successive weighting of characters yielded three most-parsimonious trees, and the strict consensus of these was well resolved. Reconstruction of the aphid?host associations on the consensus tree indicated that the ancestral Eriosomatini were associated with Zelkova and that the association with Ulmus evolved twice independently. It is suggested that despite early diversification of the Eriosomatini on Zelkova species, Zelkova-associated eriosomatines had become extinct or survived as relict parthenogens on the secondary host since the late Tertiary. In contrast, two large genera in the Eriosomatini, Eriosoma and Tetraneura, are associated with the largest elm section Ulmus whose elements are distributed widely in Eurasia, including boreal regions. Therefore, the available evidence suggests that the present species diversity and distribution patterns of the eriosomatines have been largely affected by the diversification and extinction of their host plants during the late Tertiary and Quaternary.

Patterns of diversification of the conifer feeding-aphid genus *Cinara* (Lachnidae): Biogeographical history and evolution of host plant association

Emmanuelle Jousselin[1], Armelle Coeur d'acier[2]
[1]INRA-EFPA, France, [2]INRA, France

Cinara is a large genus of Aphididae, with 222 species, specialized on Gymnosperms, mainly on the genus Pinus. It is commonly thought that the conifer-feeding genus Cinara, had an angiosperm-feeding ancestor and secondarily acquired its coniferous hosts. This shift appears to be associated with a recent successful radiation onto a young conifer family (Pinaceae). Speciation within this genus is said to be mostly driven by host switch. The aims of our study are: (i) to produce a robust molecular phylogeny of the genus and explore the validity of the taxonomic subdivisions, (ii) to use this reconstruction to study patterns of diversification in this genus, we will investigate the respective roles of host-plant association, biogeographical history and aphid feeding sites. Using more than 200 specimens, representing 58 species, we built a molecular phylogeny with 6 DNA fragments (mitochondrial, nuclear and Buchnera aphidicola). Our phylogenetic trees confirm the monophyly of all described species however it shows that some species clearly encompass several genetic clades. We therefore used a DNA species delimitation method to produce a species tree. The mapping of host plant association on this reconstruction reveal several major switches between genera Pinus and Picea during Cinara's evolution. Biogeographical reconstructions also suggest several dispersal events between Europe and North America. Evolutionary transitions in Cinara's feeding sites have also accompanied Cinara's speciation events. We discuss alternative scenarios for the rapid diversification of this aphid genus.

Population genetic structure of the cotton-melon aphid, *Aphis gossypii* Glover, in primary and secondary hosts

Hyojoong Kim[1], Yerim Lee[2], Seunghwan LEE[3]

[1]Kunsan National University, Republic of Korea, [2]Seoul National University, Republic of Korea, [3]Seoul National University, Republic of Korea

Population diversification due to host-specialized populations in the polyphagous cotton-melon aphid, Aphis gossypii, is remarkable among all aphid species. Aphis gossypii utilizes 148 plant species as host plants in which those host-varied populations possibly speciated or genetically isolated into several populations. These hosts are classified into primary (winter) and secondary (summer) hosts; the former specialized for mating and oviposition, and the latter for proliferation by parthenogenetic reproduction. It is known that some strains of A. gossypii can alternate primary and secondary hosts in the temperate region. Because secondary hosts diverse further than primary hosts, it is suggestive that genetic diversity increase when different populations isolated by secondary hosts return to interbreed there. In this study, we aim to confirm how the population isolations were correlated with host-varied, geographic, or host-preferred factors, and to clarify the pattern of population-level diversification based on population genetics. We performed population genetics using the demes alternating between winter (primary) and summer (secondary) hosts in the cotton-melon aphids. We analyzed population genetic structure between 570 aphids collected from 41 plant species of primary and secondary, mostly wild, hosts using 9 microsatellites loci. As results, population structure revealed that several genetic affinities in use of some secondary and primary hosts are detected. Host preference in secondary host is higher than that in primary host, and woody plants share same genetic structure. We will discuss whether these aphid species speciated by the related mechanisms such as host alternation and loss of primary host.

Review COI seqeunces of the Aphididae, and the necessity of developing new molecular markers for aphid species identification

Wonhoon Lee[1], Robert G. Foottit[2], Seunghwan Lee[3]

[1]Graduate School of Agriculture, Hokkaido University, Japan, [2]Invertebrate Biodiversity, Agriculture and Agri-Food Canada, Canada, [3]Seoul National University, Republic of Korea

Several DNA barcode studies were conducted on the family Aphididae, reporting the usefulness of the mitochondrial COI gene as DNA barcodes in identifying aphid species. However, it sometimes caused misidentifications mainly due to low interspecific genetic divergences among some aphid species. In this study, to determine useful molecular markers to improve this problem, 1,257 sequences of the ten genes (COII, CytB, ATP6, lrRNA, srRNA, ITS1, ITS2, EF1a, 18S, and 28S) were examined along with 1,019 sequences of COI gene. Our analyses showed that the ATP6 gene revealed higher genetic divergences than those of COI at conspecific and congeneric taxonomic levels. The possibility of the ATP6 gene as an alternative molecular marker was explored by using it to identify thirty aphid species, confirming that ATP6 gene is suitable marker to improve on the rate of misidentifications.

Reconstruction of subtribal concept in the tribe Macrosiphini (Hemiptera: Aphididae) based on molecular data

Hwalran Choi[1], Seunggwan Shin[2], Seunghwan Lee[3]

[1]Seoul National University, Republic of Korea, [2]Seoul National University, Republic of Korea, [3]Seoul National University, Republic of Korea

The tribe Macrosiphini is one of the largest group within family Aphididae, comprising near 50% of the 5000 described species. According to previous studies of aphids, the phylogenetic relationship of Macrosiphini has been controversial and still ambiguous at the subtribal level. With the results of comprehensive molecular phylogenetic study by Bayesian phylogeny (BP) and Maximum-likelihood (ML) using combined data sets of molecular sequences (cytochrome oxidase I (COI), tRNA-leucicne+cyrochrome oxidase II (tRNA+COII), 16S ribosomal RNA (16S rRNA) and Elongation factor-1 alpha gene (EF1α)), we reconstruct the subtribal groups for the tribe Macrosiphini.

Phylogeography, life cycle evolution and differentiation of sibling species in the leaf-curling plum aphid, *Brachycaudus helichrysi* (Hemiptera : Aphididae).

Josephine Piffaretti[1], Flavie Vanlerberghe-Masutti[2], Emmanuelle Jousselin[3]
[1]UMR CBGP - INRA, France, [2]UMR CBGP - INRA, France, [3]INRA, France

Brachycaudus helichrysi is a worldwide polyphagous aphid pest that seriously damages its primary hosts (Prunus spp.) and the various cultivated plants among its secondary hosts (e.g. sunflower, Chrysantemum). In a recent phylogenetic study based on worldwide sampling, we have shown that this species is actually an amalgamation of two sibling taxa, B. helichrysi H1 and B. helichrysi H2. This study based on mitochondrial, nuclear and Buchnera aphidicola DNA markers revealed that these two taxa display levels of genetic divergence as great as those generally found between sister species in the Brachycaudus genus, suggesting that they correspond to two distinct species. Further investigations, based on microsatellites data combined with ecological information suggest that these two species have two very different evolutionary histories. B. helichrysi H1 exhibits a typical signature of a heteroecious life cycle on plum trees, and we demonstrate the existence of distinct geographic genetic clusters within this "species". By contrast B. helichrysi H2 gather two types of lineages. First, we demonstrate the existence of several persistent clonal lineages, distributed worldwide and highly polyphagous. Second, we found a heteroecious lineage that use peach trees as primary hosts and has so far only been found in found in Asia. All B. helichrysi lineages can be found in mixed colonies on herbaceous hosts all around the world. At some locations, individuals exhibit introgressed genotypes between B. helichrysi H1 and H2. We discuss how life cycle evolution, leading to reproductive barriers, could explain the ongoing speciation in the B. helichrysi species complex.

Evolution of asexuality in the pea aphid, *Acyrthosiphum pisum*

Takashi Kanbe[1], Shin-ichi Akimoto[2]

[1]Hokkaido University, Japan, [2]Hokkaido University, Japan

Many aphid species include asexual lineages that are often distributed in the southern region of the distribution range. Asexual lineages could originate through spontaneous loss of sexuality arising from environmental conditions or mutation, or hybridization between closely related species or host races. In the present study, we examined how asexual lineages of A. pisum originated in East Asia by using genetic and phylogenetic methods. In northern regions of Japanese islands, sexual host races were associated with Vicia cracca, Vicia angustifolia, alfalfa and clover. Asexual lineages of A. pisum were found widely on Vicia angustifolia in the main island of Japan, where each local population consisted of a few asexual clones with different genotypes. Thus, genetic diversity in asexual population was markedly limited. Analysis with microsatellites indicated that the major clones (super clones) often had considerably different constitution of alleles from each other. Phylogeny constructed using microsatellites showed that asexual populations on Vicia angustifolia did not constitute a monophyletic group with sexual populations on the same plant. Cloning and sequencing of EF1α alleles from each asexual individual indicated that a part of these individuals contained an allele that was specific to sexual populations on Vicia cracca and a different allele that was specific to sexual populations on Vicia angustifolia. Therefore, our results suggest that in A. pisum, the origin of asexual lineages is partly ascribed to hybridization between different sexual host races, as indicated for Rhopalosiphum padi by Delmotte et al. (2003).

Systematics, Phylogeny and Zoogeography

Host-associated differentiation among host-sharing aphids in the gossypii group

YERIM LEE[1], Seunghwan Lee[2], Hyojoong Kim[3]

[1]Department of Agricultural Biotechnology, Seoul National University, Korea, Republic of Korea, [2]Seoul National University, Republic of Korea, [3]Kunsan National University, Republic of Korea

Insect herbivores, especially aphids, are closely related with their host plants, which are crucial for their life as the only habitat as well as food resources. Current species-richness of aphids is highly associated with their complex life cycles including host alternation and cyclical parthenogenesis on various host plants. Host alternation is considered one of the most critical factors for their differentiation driven by loss of primary host. Interestingly, both monoecious and heteroecious aphids exist in the gossypii group belonging to the most species-rich genus Aphis. In this study, we examined genetic structure of four heteroecious species, Aphis gossypii Glover, A. glycines Matsumura, A. sp. ex Rhamnus, and A. punicae Passerini, in gossypii group using mitochondrial COI sequence and 9 cross-species-amplifiable microsatellite loci. These four closely-related species occur together on several primary and/or secondary hosts: Rhamnus, Rubia, Punica and Commelina. We also identified four genetically differentiated clusters associated with Hibiscus, Rhamnus and several secondary hosts within A. gossypii. Majority of secondary-host-associated populations were affinitive with the Hibiscus-associated group, whereas several host races collected from Sedum and Ixeris were considerably differentiated with Hibiscus-associated group. These high divergences might be caused by loss of primary host. Some incongruities between COI and microsatellite genotypes, and our confirmation of inter-specific copulation suggest that there would be a continuous gene flow between host-sharing species of the gossypii group in same primary host as a hybrid zone.

Systematics, Phylogeny and Zoogeography

Phylogeny and social evolution of the Halictidae

Jason Gibbs[1], Sean Gary Brady[2], Kojun Kanda[3], Bryan N. Danforth[4]

[1]Cornell University, U.S.A., [2]Smithsonian Institution, U.S.A., [3]Oregon State University, U.S.A., [4]Cornell University, U.S.A.

The bee family Halictidae is one of the most interesting groups of insects from the perspective of social evolution. More behavioural diversity is present in the halictid bees than any other comparable taxon. The halictid bees were once thought to have evolved eusociality 'many' times. New phylogenetic results - focussed on the tribe Halictini, which includes the most behaviourally diverse genera - and model-based ancestral state reconstruction suggest fewer and more ancient origins of eusociality than previously believed.

Phylogeny and macroevolution of colletid bees (Hymenoptera: Colletidae)

Eduardo A. B. Almeida[1], Marcio R. Pie[2], Sean G. Brady[3], Bryan N. Danforth[4]

[1]Universidade de Sao Paulo (USP), Brazil, [2]Universidade Federal do Parana, Brazil, [3]Smithsonian Institution - National Museum of Natural History, U.S.A., [4]Cornell University, U.S.A.

Colletid bees have been viewed as a prime example of an ancient group whose Gondwanan origin could have preceded the complete breakup of Africa, Antarctica, Australia and South America, because modern lineages of this family occur primarily in southern continents. The diversification of colletid bees was investigated to elucidate processes that may have contributed for the present diversity as well as southern disjunctions. A data set comprising four nuclear genes of a broad sample of Colletidae was assembled and Bayesian inference analyses to estimate the phylogenetic relationships as well as divergence times. Lineage-through-time analyses were used to explore the tempo of radiations of Colletidae and its context in the biogeographical history of these bees. Initial diversification of Colletidae took place at the Late Cretaceous (≥ 70 Ma). Several lineage exchanges between Australia and South America through Antarctica during the Late Cretaceous through the Late Eocene could explain the disjunctions observed between colletid lineages today. Higher diversification rates in the later period of colletid history were detected. From these findings, it can be concluded that biogeography and macro-evolutionary history of colletid bees is explainable by a combination of Cenozoic vicariance and palaeoclimate changes during the Neogene. The austral connection followed by breakup of Antarctica, Australia, and South America resulted in disjunct sister-lineages in the latter two continents. Increased biome aridification coupled with floristic diversification in the southern continents during the Neogene may have contributed to the high rates of cladogenesis of these bees in the last 25-30 Myr.

Systematics, Phylogeny and Zoogeography

Recurrent evolution of dependent colony foundation in the aculeata

Adam L. Cronin
Iwate University, Japan

Eusocial insects are often championed as icons of cooperation and specialization, yet in the majority of species new colonies are initiated by a solitary queen acting alone. In many bees, ants and wasps, selection against this solitary phase has lead to the recurrent evolution of dependent colony foundation (DCF; also known as fission, swarming and budding), whereby new colonies are founded by groups of individual nestmates. While this strategy is widespread, and characteristic of some of the most ecologically and economically important species (eg: honeybees, stingless bees, army ants), it remains poorly understood. Furthermore, adoption of dependent colony foundation has implications for diverse phenomena including population genetics, dispersal, reproductive investment, invasiveness, morphology and ecological flexibility. In this presentation I review the phylogenetic distribution of DCF across the aculeata, and summarise data from some recent studies on ants. DCF is both more widespread and more diverse than generally acknowledged, and more studies focusing on DCF are needed.

Radiation of the allodapine bees since the Eocene

Luke B. Chenoweth[1], Michael Philip Schwarz[2]

[1]Flinders University, Australia, [2]Flinders University, Australia

Allodapine bees are largely restricted to the southern Old World and provide an ideal group for exploring Southern Hemisphere historical biogeography and the effects of climate change associated with establishment of the Circumpolar Current. The Allodapini originated in Africa and there have been multiple dispersals to Asia, the Middle East, Madagascar and Australia. Here we show that radiations in Australia and Africa show very different historical patterns od diversification. The Australian radiation is marked by a strong response to aridification in the Miocene, probably the result of increased allopatric speciation as cooler habitats became fragmented, but such a response is absent in Africa. Our results indicate very different responses to climate change at a continental level and suggest that future responses of even closely related taxa are likely to vary enormously among southern landmasses.

Radiation of bees in the South West Pacific - Dispersals and rapid radiations

Scott V. C. Groom[1], Mark I. Stevens[2], Michael P. Schwarz[3]

[1]Flinders University, Australia, [2]South Australian Museum, Australia, [3]Flinders University, Australia

Although bees form a key pollinator suite for flowering plants, very few studies have examined the evolutionary radiation of non-domesticated bees in human time-scales. This is surprising given the importance of bees for crop pollination and the effect of humans in transforming ecosystems via agriculture. Here we explore the radiation of halictine bees in Fiji following their post-Miocene colonization of these islands. Our mtDNA barcode data indicate the existence of several 'deep' clades whose divergences are close to the crown node, along with another highly derived 'broom head' clade with very high haplotype diversity mostly limited to low-lying agricultural regions. Whilst this derived clade is very abundant, the more basal clades were relatively rare. Although nearly all haplotype diversity in Fijian Homalictus comprises synonymous substitutions, a small number of amino acid changes are associated with the major clades, including the hyper-diverse clade. Analyses of haplotype lineage accumulation show a steep increase in selectively neutral COI haplotypes corresponding to the emergence of this 'broom head' clade. We explore three possible scenarios for this dramatic increase: i) a key change in adaptedness to the environment, ii) large-scale extinction event, or iii) a dramatic increase in suitable habitats leading to rapid population expansion. Using estimated mutation rates of mitochondrial DNA in other invertebrates, we argue that this increase may coincide with a period of agricultural intensification in populated coastal areas. Our results indicate that non-domesticated bee species may have responded strongly to human activities, and we discuss the implications of this finding.

Systematics, Phylogeny and Zoogeography

Phylogenetic perspective of a nocturnal niche invasion

Simon M. Tierney
Flinders University, Australia

Comprehending how bees invade, or create, novel niches greatly enhances our understanding of the process of evolution. Behaviour is often the driving force of change, while genetic modifications permit adaptations that take advantage of these novel behaviours, and allow us to track their evolution. Most bees forage in bright sunshine, but some linegaes visit flowers in very dim-light, or are fully nocturnal; which is proposed as a response to competition, predation and parasitism. The sweat bee tribe Augochlorini contains the most diverse lineage of dim-light foraging bees. Their phylogenetic history, based on three nuclear genes (2K nucleotides), suggest a single origin (approx. 22 Mya), with at least one reversion to diurnal foraging from a nocturnal ancestor. Analysis of the longwavelength (green) opsin gene suggest a functional mutation of an amino acid - at the site where the chromphore binds to the opsin protein, that theoretically enables vision at alternate wavelengths. The implications of these findings are discussed in light of recent discoveries in opsin biology and the functional link between opsin evolution and circadian rhythm. The phylogenetic history of closely related species that inhabit alternate light environments provide the ideal system to explore these connections. Circadian rhythm in castes of highly social insects show periodicity dependent on behavioural reportoire, and the relationships between circadian clock evolution and social castes is discussed.

Systematics, Phylogeny and Zoogeography

Evolution of sociality in the apoid wasp *Microstigmus nigrophthalmus*

Eric R. Lucas[1], Rogerio P. Martins[2], Lorenzo R. S. Zanette[3], Jeremy Field[4]

[1]University of Lausanne, Switzerland, [2]Universidade Federal de Minas Gerais, Brazil, [3]Universidade Federal do Ceara, Brazil, [4]University of Sussex, United Kingdom

The order Hymenoptera is rich in origins of social behaviour, yet several of these remain very little studied. Microstigmus is a neotropical genus of apoid wasps which represents an origin of sociality independent of vespoids. Until recently, studies of colony genetic structure in this clade were limited to one species, M. comes. Combining experimental manipulation, behavioural observations and hypervariable genetic markers, we investigated the social and genetic structure of M. nigrophthalmus, a species from the Atlantic forest habitat of Brazil, known to nest in groups. We found that M. nigrophthalmus exhibits an unusual social system that differs from both M. comes and vespoids: there is cooperative brood care, and several females may share reproduction in the same nest, but it appears to be these reproductive females that perform most of the foraging effort. We also investigated the potential benefits to sociality in this species. Mean relatedness between female nestmates was high (0.49), so that females obtain indirect benefits through helping, but relatedness was very variable and could be very low in some nests. Furthermore, experimental removal of reproductive females from the nest revealed that orphaned brood continued to be cared for by surviving nestmates, indicating that a group-nesting female could benefit from the insurance that her offspring will continue to be raised to adulthood in the event of her death (Assured Fitness Returns).

Antiquity and evolutionary history of sociality in carpenter bees

Sandra Rehan
University of Pennsylvania, U.S.A.

Understanding how advanced social organization has evolved comprises one of the key puzzles in evolutionary biology. We know that once this kind of social complexity evolves it can be enormously successful, but we also know that it has evolved very, very rarely. The paradox of why such an enormously successful strategy has evolved so rarely is one of the major questions facing evolutionary biology. Resolving this critical paradox is very difficult because most of the socially complex species have few surviving relatives that are solitary, so we are unable to examine the evolutionary stages leading from simple to complex organization. The bee subfamily Xylocopinae contains four extant tribes. Three of these, the Allodapini, Xylocopini and Ceratinini, have been extensively used to investigate social evolution. The fourth tribe, Manueliini contains species whose biology has been largely unknown until very recently. It is important to understand the phylogenetic position of Manueliini so we can explore, whether sociality is plesiomorphic for the Xylocopinae or whether it evolved multiple times in this subfamily. Using phylogenetic inference and nesting biology studies on 34 species across all four tribes reveals that a weak form of sociality is ancestral for the Xylocopinae, and was in place for over 90 million years. In this subfamily the earliest societies did not entail a foraging worker caste, but instead comprised females sharing a nest with supersedure of dominance.

Evolutionary patterns of hind wing morphology in scarabs (Coleoptera: Scarabaeoidea) based on the extant and extinct evidences

Ming Bai[1], Junzhi Cui[2], Xingke Yang[3]
[1]Chinese Academy of Sciences, China, [2]Chinese Academy of Sciences, China, [3]Chinese Academy of Sciences, China

The shape of wings can be a good predictor of adaptations to different selective pressures and the value of wing features in taxonomy and phylogeny has long been recognized. Previous studies have analyzed the evolution of wing shape within a single or very few species, or by comparing only a few wing traits. No study has analyzed wing shape evolution of a large number of species, or quantitatively compared morphological variation of wings with proposed phylogenetic relationships. Two of our studies examined the morphological variation of hind wings based on 19 landmarks, 119 morphological characters, and 81 beetle species. Another two studies published two new fossil families of Scarabaeoidea, based on the geometric morphometrics analysis of hind wings and cladistic evidences. In our investigations of the hind wing evolution of scarabs, we use geometric morphometrics combined with a cladistic approach. The tools of geometric shape analysis have a tremendous advantage in this application: it does not only offer precise and accurate descriptions, but also serves the equally important purposes of visualization, interpretation and communication of results.

Phylogenetic relationships of Cleroidea

Richard Leschen[1], John Lawrence[2], Adam Slipinski[3], Matthew Gimmel[4]
[1]Landcare Research, New Zealand, [2]CSIRO, Australia, [3]CSIRO, Australia, [4]University of Kansas, U.S.A.

Members of Cleroidea (Cucujiformia) were once included in a broadly-defined Clavicornia along with tenebrionoids and cucujoids, while those having soft bodies like Melyridae were placed in Malacodermata with cantharoids and other taxa. Now, Cleroidea consists of 10 families and is usually considered monophyletic based on the absence of a mandibular mola in adults and larvae, basal mandibular processes (lacinia mobilis) present in larvae, and a pedunculate seta present on the mala. Phylogenetic relationships among the family-groups of cleroids is far from settled, and in the latest phylogeny of Lawrence et al. (2011), the cleroids were polyphyletic, made so by the placements of some members of the Trogossitidae outside Cleroidea as sister taxa to two separate cucujoid groups. Moreover, the remaining trogossitids contained within the superfamily formed a rather messy grade, indicating that a more detailed look at Trogossitidae is required to better understand character distributions and paraphyly with regard to the entire Cucujiformia. A first step is an appraisal of trogossitids and we present a local phylogenetic study of cleroids to address the issue of trogossitid polyphyly. We derive a more restricted data set from Lawrence et al. (2011) composed of all cleroid families and selected out-taxa from major groups of Cucujiformia. We also include observations made from confirmed larvae of the gondwanan trogossitid subfamily Rentoniinae. With the addition of new data, we confirm Trogossitidae paraphyly, as well as non-monophyly of other cleroid families. We advocate a reclassification of the Trogossitidae with the recognition of at least one new family.

The Phylogeny of Tenebrionoidea (Cucujiformia) inferred from molecular data

Kojun Kanda[1], Alexander Wild[2], Duane Mckenna[3], David Maddison[4]

[1]Oregon State University, U.S.A., [2]University of Illinois, U.S.A., [3]University of Memphis, U.S.A., [4]Oregon State University, U.S.A.

The Tenebrionoidea are a morphologically and ecologically diverse lineage of over 35,000 species of beetles. We report recent phylogenetic findings on the relationships within this superfamily. Three nuclear protein-coding genes (Argk, CAD, wg) and one ribosomal gene (28s) were sampled across 120 taxa representing all 28 currently recognized families in the Tenebrionoidea. Diverse lineages of Cucujiformes were also sampled to examine the superfamily's monophyly. Likelihood analyses supports the monophyly of the Tenebrionoidea with the inclusion of the Lymexylidae and also suggest the need for redefining the limits of some of the families (e.g. Tenebrionidae, Mycteridae). We also discuss the major clades recovered by our datasets and compare these to existing phylogenetics hypotheses for the group.

Phylogenetics of weevils (superfamily Curculionoidea)

Adriana Elena Marvaldi[1], Duane McKenna[2], Brian Farrell[3]

[1]CONICET, Argentina, [2]University of Memphis, U.S.A., [3]Harvard University Museum of Comparative Zoology, U.S.A.

The monophyly of the Curculionoidea (weevils) is supported by both molecular and morphological evidence. Recent phylogenetic studies also indicate that the Chrysomeloidea (leaf beetles and long-horned beetles) are their closest relatives, forming together a clade "Phytophaga" within the Coleoptera Cucujiformia. The present contribution will focus on the evolutionary history of the Curculionoidea, with approximately 62,000 described extant species, 80 % of which belong to the family Curculionidae. Being so extraordinarily speciose, the phylogenetic systematics of weevils remains most challenging. An updated molecular phylogeny of weevils is presented, based on analysis of DNA sequences from two nuclear (entire18S rRNA and segments D2-D3 of 28S rRNA) and two mitochondrial (domains IV-V of 16S rRNA and COI-3' section) markers, from a worldwide sample now expanded to include approximately 200 weevil genera and several outgroups. The gene fragments chosen are commonly sequenced for phylogenetic studies of Coleoptera and other insects. Here, the alignment of the sequences from ribosomal genes (18S, 28S, and16S) was performed according to secondary structural information, a method that uses a biological criterion (covariation) for assigning positional nucleotide homology. The value of incorporating structural information in the process of alignment is highlighted. Besides recovery of nodes consistent with major weevil lineagespreviously defined by adult and larval synapomorphies, molecular evidence from this study contributes to resolving controversial areas of weevil phylogeny, for example, the "platypodine problem", and to helping identify main clades within the megadiverse Curculionidae. A succinct account is given of the major groups, summarizing their diversity, fossil information, and biology.

Nomenclature of family-group and genus-group names in Coleoptera

Pat Bouchard[1], Miguel A. Alonso-Zarazaga[2]
[1]Canadian National Collection of Insects, Canada, [2]Museo Nacional de Ciencias Naturales (CSIC), Spain

The most recent International Code of Zoological Nomenclature (ICZN 1999) included a new article entitled List of Available Names in Zoology (LAN). The goals of this Article are to promote nomenclatural stability by summarizing data on all available names, in a particular group and at a particular rank, by paring away dubious names in the literature and ensuring that such list is thoroughly vetted by experts. The Commission has received two submissions for Parts of the LAN to date (family-group names in Aphidoidea and species-group names in Rotifera) but none have been adopted yet. Coleopterists recently synthesized data on extant and fossil Coleoptera family-group names for the first time (Bouchard et al. 2011). Nearly 4500 suprageneric names were determined to available. For each name, the original spelling, author, year of publication, page number, correct stem and type genus were included. Genus-group names in Coleoptera have attracted much more attention from authors interested in nomenclature, usually specialists working on one or a small number of families. The results of these efforts have been the production of numerous catalogues sometimes with broadly variable interpretations of nomenclatural acts for similar problems in different groups. In our presentation, we will outline our plans for submitting a Part of the LAN relating to family-group names in Coleoptera in the near future. In addition we will discuss the potential establishment of a major collaborative effort with the ultimate goal to one day submit a Part of the LAN relating to genus-group names in Coleoptera.

Reconstructing the Beetle Tree of Life

Duane D. McKenna[1], Alex Wild[2], Kojun Kanda[3], David Maddison[4], Brian D. Farrell[5]
[1]University of Memphis, U.S.A., [2]University of Illinois, Urbana-Champaign, U.S.A., [3]Oregon State University, U.S.A., [4]Oregon State University, U.S.A., [5]Harvard University, U.S.A.

The lack of a relatively comprehensive and well-supported phylogeny for beetles (Coleoptera) has left us with many lingering questions about beetle relationships and has hampered efforts to reconstruct timing and patterns of beetle evolution. In this talk I will present an overview of beetle relationships based on analyses of nuclear DNA sequence data from the Beetle Tree of Life Project. I will discuss relationships across the order Coleoptera, but my presentation will be focused on the extraordinarily diverse suborder Polyphaga. Within Polyphaga I will discuss relationships among lower-level groups, e.g., series, superfamilies and families. Additionally, I will highlight some success stories while also noting groups whose interrelationships remain unclear.

A summary tree of Coleoptera from available molecular data

Alfried P. Vogler[1], Chris Barton[2], Douglas Chesters[3], Ladislav Bocak[4], Alexandra Crampton-Platt[5], Sujatha N. Kutty[6], Dirk Ahrens[7]

[1]Natural History Museum, United Kingdom, [2]Natural History Museum, United Kingdom, [3]Natural History Museum, United Kingdom, [4]University of Olomouc, Czech Republic, [5]Natural History Museum, United Kingdom, [6]Natural History Museum, United Kingdom, [7]Museum Koenig Bonn, Germany

The growing database of publicly available DNA sequences provides an increasingly detailed picture of the phylogenetic relationships of Coleoptera. We present a single tree of >8000 species based on the most widely used genetic loci. Our recent efforts aimed at 'gap filling' of unsampled lineages and missing loci has greatly reduced the inconsistencies of previous compilation from GenBank sequences. The resulting tree is a now satisfactory framework for placing incoming new sequences, including environmental samples, and permits reliable placement of unknown samples based on a range of loci. Already many incompletely identified sequences complicate tree building and concatenation of sequence data across loci, but we have developed methods that minimize these problems. Besides methodological aspects of building very large trees from data mining, the talk will also discuss the increasingly well supported basal relationships of Coleoptera.

Systematics, Phylogeny and Zoogeography

Origin of views on origins of hexapods

Niels Peder Kristensen
Natural History Museum of Denmark, Denmark

To Linnaeus all arthropods were 'Insecta', with the non-pterygotes (including some secondarily wingless pterygotes) grouped into the order 'Aptera'. A refined systematization of the 'Aptera' was initiated by his foremost entomologist student Fabricius and continued by Latreille, who eventually excluded crustaceans, arachnids and finally myriapods from 'Insecta'. A concept of 'origin' evidently required evolutionary thinking, and Haeckel depicted hexapods on a 'phylogenetic tree', sharing with the myriapods a branch from the 'Tracheata' stem, which in turn is shared with the arachnids, and joins the Malacostraca stem before that of the entomostracans. Symphyla were so named (Ryder 1880) exactly to emphasize their "singular combination of myriapodous, insectan and thysanurous characters"; a concept of symphylans being particularly relevant for elucidating hexapod origins remained advocated by outstanding 20th century writers. The distinction between primarily and secondarily wingless hexapods was introduced first by Brauer and Lubbock, but Brauer's fellow-countryman Handlirsch later derived the pterygotes directly from tilobites, not from apterous hexapods. While the 'Tracheata'/'Atelocerata' concept had the upper hand throughout most of the 20th century, close Crustacea+Hexapoda affinities were not without advocates during its first half. Even hexapod non-monophyly was given serious consideration, with Collembola being outside a lineage comprising myriapods and other hexapods (Imms), or with a taxon 'Myocerata' comprising entognathans+myriapods being opposed to the Insecta s.str. ('Amyocerata', Remington). However, apart from the 'Mantonian interlude' (concepts of otherwise unimagined polyphyly of arthropod lineages), a monophyletic Entognatha+Insecta being the sister group of myriapods, or a subgroup thereof, appeared a near-consensus model until the 1990s.

Systematics, Phylogeny and Zoogeography

How did the first hexapod look like: Status quo and problems in reconstructing the ground pattern of Hexapoda

Nikolaus Urban Szucsich
University of Vienna, Austria

Our knowledge on the ground pattern of the morphology of Hexapoda is still quite limited for several reasons. Despite the high agreement that hexapods are nested within paraphyletic crustaceans, the precise hexapod sister group within Pancrustacea is still hotly debated. Many older attempts to reconstruct the ground pattern of Hexapoda mostly were based on a hypothesized sister group relationship with myriapods, or a subgroup of the latter. Other attempts to reconstruct the first hexapod are not based on outgroup comparison, but on sometimes not explicitly mentioned assumptions regarding the nature of character evolution. Additionally, the reconstructed ground pattern often only reflects the situation in Archaeognatha and Zygentoma, while the entognathous groups are implicitly assumed to secondarily display more derived conditions. Selected character systems will be chosen to highlight problems in the ground pattern reconstruction. Partly character polarization based on empirical data allows for no unambiguous reconstruction of the ground pattern. In other instances, however, reevaluation of character system results in phylogenetically informative characters, with strong impact on our insights into both character evolution and phylogeny.

Exploring morphological variation in apterygotes: Consequences of taxon sampling on ancestral character state reconstructions

Markus Koch
University of Hamburg, Germany

Previous attempts to infer the early evolution of hexapods from comparative morphology are based on only a few, more well-known apterygote exemplars. In recent years some lesser-known taxa have been included into cladistic analyses and characters of internal anatomy have been explored to cover phenotypic variation more comprehensively. The current taxon sampling especially includes projapygoids and non-japygid Dicellurata among Diplura, as well as the Nicoletiidae, Protrinemuridae, and Maindroniidae among Zygentoma. Based on the new sampling the ancestral character states for each of the apterygote orders are revised and used for discussion of the basal splits among hexapods. Current insights reveal a remarkable degree of homoplastic transformations during the early evolution of hexapods, including convergent gain of characters related to terrestrial life habits. The phylogenetic resolution of the Diplura among apterygotes has the most drastic impact on our understanding of the hexapod ground pattern, whereas the contribution of extinct apterygote taxa presently remains ambiguous. Outgroup comparison with crustaceans still is a major deficiency in comparative hexapod morphology. In order to contribute to a clarification of the hexapod origin, one imminent task is to reevaluate many anatomical characters that are presently considered as mutually inapplicable in analyses of crustacean and hexapod phylogeny.

Systematics, Phylogeny and Zoogeography

Early splitting of Hexapoda reviewed from the comparative embryology

Ryuichiro Machida
University of Tsukuba, Japan

Phylogenetic relationships of hexapod basal clades have been greatly debated from multiple sources, but are still not satisfactorily resolved. For example, doubt has been cast on the reality of the Entognatha-Ectognatha system, especially regarding the status of Entognatha. In the past few decades, much embryological knowledge concerning Apterygota has been accumulated. I discuss the early splitting of hexapod basal clades and phylogenetically reconstruct them based on recent progress of apterygote comaprative embryology. Comparative embryological analyses on the basal clades of Hexapoda demonstrate an anagenetical transition of the functional specialization between embryonic membranes and embryo proper, leading to the acquisition of elaborated structures derived from the embryonic membranes. Hereby, the basal splitting of Hexapoda may be formulated as: Ellipura (= Protura + Collembola) + (Diplura + Ectognatha (= Archaeognatha + Dicondylia (= Zygentoma + Pterygota))). Ellipura is supported, but Entognatha is dismissed. Comparison of entognathy formations among three "entognathan" orders reveals a close resemblance between Protura and Collembola but a marked contrast between Diplura and Ellipura (the detail is given in the talk by Tomizuka et al.). Also as for other embryological features such as the manner of germ band (= embryo) formation and that of the primary dorsal organ, the congruency between Protura and Collembola and the discrepancy between Ellipura and Dilura are revealed. On the other hand, it should be noticed that Diplura and Ectognatha share the possession of a second embryonic membrane or the amnion, which may be regarded as being an embryological synapomorphy of Diplura and Ectognatha.

Entognathy formations of three entognathan constituents, Protura, Collembola and Diplura

Shigekazu Tomizuka[1], Kaoru Sekiya[2], Makiko Fukui[3], Ryuichiro Machida[4]
[1]University of Tsukuba, Japan, [2]University of Tsukuba, Japan, [3]Ehime University, Japan, [4]University of Tsukuba, Japan

Recently, "Entognatha-Ectognatha System" has been challenged, and doubt has been cast on the interordinal relationships within and monophyly of Entognatha from multiple sources. Entognathy has been regarded as a most reliable "autapomorphy" of Entognatha. We compare the entognathy formations of Protura, Collembola and Diplura, examine the homology of their entognathies, and discuss the interordinal relationships and monophyly of Entognatha. Protura and Collembola are revealed to closely resemble each other in major points of entognathy formation, such as concerning: 1) the origin of mouth folds, which are formed by the extension and fusion of terga of intercalary and three gnathal segments, and 2) origin of the postgnathal region of entognathy, which is derived from labial terga medially migrated and united. However, the entognathy of Diplura is constructed in a different manner, which is characterized by: 1) the mouth fold is formed by the fusion of extended terga of intercalary and three gnathal segments and labial coxa, 2) the postgnathal region of entognathy is derived from labial subcoxae which medially migrate and unite into a form of postmentum, and 3) the rotation of labial appendages is involved in the entognathy formation. The homology of entognathy is well supported between Protura and Collembola, hence the monophyly of Ellipura may be supported. While the manner of entognathy formation in Diplura is revealed to be much different from in Protura and Collembola either, hence the homology of entognathy between Protura-Collembola and Diplura is not always verified, and the monophyly of Entognatha could not be substantiated.

Unravelling Collembola phylogeny

Cyrille A. D'Haese
UMR7205 CNRS-MNHN, France

Among the three entognathan classes of hexapods (Protura Diplura and Collembola), springtails are arguably the most important. Their relationships have been discussed since the early 20^th century and despite recent attempts to solve their phylogeny, both from morphological and molecular data analyses, relationships among the main lineages and the very position of Collembola within Hexapoda are still largely open to debate. Multiple molecular loci and morphology for a broad taxonomic sampling are analysed through Direct Optimization to address the placement of Collembola, the four orders Neelipleona, Symphypleona, Entomobryomorpha and Poduromorpha, along with the familial relationships within the orders.

The molecular evolution of basal hexapods

Yun-Xia Luan[1], Wan-Jun Chen[2], Ya-Nan Hou[3], Yun Bu[4], Yan Gao[5], Wen-Ying Yin[6]

[1]Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, China, [2]Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, China, [3]Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, China, [4]Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, China, [5]Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, China, [6]Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, China

We have studied the phylogenetic positions of basal hexapods (Protura, Collembola and Diplura) by molecular approach for more than ten years. 18S, 28S rRNA genes, mitochondrial genomes and some nuclear protein-coding genes of the representative species from basal hexapods were sequenced and analyzed together with those of other arthropods. Our studies suggested it's hard to get a consistent tree and robust supporting values for the phylogenetic position of Protura, Collembola and Diplura by analyzing different molecular markers. Now, we are working their transcriptome data, and hope to figure out the most appropriate molecule markers for reconstructing the phylogeny of basal hexapods in Arthropoda.

Phylogenetic analysis based on three nuclear DNA-encoded protein sequences confirms the monophyly of Hexapoda, but does not support the monophyly of Entognatha

Zhi-Hui Su[1], Go Sasaki[2], Keisuke Ishiwata[3]
[1]JT Biohistory Research Hall, Japan, [2]JT Biohistory Research Hall, Japan, [3]Osaka University, Japan

Molecular phylogenetic analyses have revealed that Hexapoda and Crustacea form a common clade (the Pancrustacea), which is now widely accepted among zoologists; however, the relationships between crustaceans and hexapods, and that among the basal lineages (Protura, Collembola, Diplura, and Ectognatha) of Hexapoda are still open questions. In this study we performed phylogenetic analyses using three nuclear genes encoding the catalytic subunit of DNA polymerase delta and the largest and second largest subunits of RNA polymerase II from 64 species of arthropods including all the hexapod orders. The amino acid sequences of these genes were subjected to phylogenetic inference based on the maximum likelihood and Bayesian methods. The resulting trees showed that all hexapods are clustered into a common clade with branchiopods being its sister lineage, while Crustacea is paraphyletic. Within Hexapoda, the monophyly of Entognatha (Protura, Collembola and Diplura), Ellipura (Protura + Collembola) and Nonoculata (Protura + Diplura) were not supported, and all resulting trees consistently suggested that Protura is the sister lineage to all other hexapods including collembolans and diplurans. Our results provide molecular evidence to support the possibility that Protura is the most basal lineage of hexapods, which is suggested from comparative embryology.

Basal hexapod relationships based on phylogenomic data: Progress, challenges and pitfalls

Karen Meusemann[1], Bernhard Misof[2]
[1]Zoologisches Forschungsmuseum A. Koenig, Germany, [2]Zoologisches Forschungsmuseum A. Koenig, Germany

Phylogenetic relationships among apterygote hexapod lineages (Protura, Diplura, Collembola, Archaeognatha and Zygentoma) are still a matter of debate. In the last decades, several contradicting hypotheses, for example, "Ellipura" (Protura + Collembola) vs. "Nonoculata" (Protura+ Diplura) or the monophyly vs. a para- or polyphyly of hexapods, have been supported from either morphological, developmental and molecular studies. The inclusion of all primarily wingless orders is crucial to reliably resolve deep hexapod and euarthropod relationships, but the molecular data have been very sparse for these taxa. We provide new EST data (Expressed Sequence Tags) obtained from next generation sequencing techniques (NSG) covering all primary wingless hexapod orders. Within this project in which we use phylogenomic molecular sequence data, we carefully assessed data quality (e.g., orthology prediction, alignment masking, selection of genes with advanced selection heuristics). Our results corroborate the monophyly of Nonoculata, but show the need for research on the fate of non-random signal in phylogenomic datasets.

Early splits of Pterygota: Inputs and shortcomings of the fossil record

Olivier Bethoux
France

With few mega-diverse sub-groups winged insects (Pterygota) compose the most diverse group of organisms on Earth. Multiple and comparatively recent evolutionary events are responsible for this diversity, but the acquisition of flight has been widely perceived as a trigger of a major and early radiation in the group. However the fossil record provides no conclusive evidence for such a radiation, or, more accurately, cannot be used to test this hypothesis. The earliest well-sampled faunas including Pterygota are early Late Carboniferous in age (~320 Myr ago). At this time Pterygota are represented by varied and distantly related groups, some of which already possessed refined flight capabilities, secondarily used wings as protective devices in association with cursorial locomotory behavior, and acquired specialized developmental pathways, all aspects incompatible with a near-contemporary flight-related radiation, and better suggestive of more ancient evolutionary history. Therefore it is assumed that pterygoty was acquired during the Early Carboniferous (at least), during which appropriate outcrops are rare, and, up to now, never yielded appropriate material. One of the collateral effects of this issue is that stem-relatives of the most major insect lineages (viz. palaeopterans, polyneopterans, Paraneoptera, and Holometabola) are unknown, although several stem-relatives at the ordinal level are well documented. Until productive outcrops are discovered, the 'Pterygota radiation' must be considered as speculative.

Resolving the phylogeny of non-endopterygote Hexapoda

Andreas Zwick[1], Hong Zhao[2], Jerome C. Regier[3]
[1]State Museum of Natural History Stuttgart, Germany, [2]Smithsonian Institution, U.S.A., [3]University of Maryland, U.S.A.

The origin and higher phylogeny of Hexapoda has been a topic of intense debate for decades, in particular the interordinal relationships. Relatively recent molecular data of Arthropoda support a sistergroup relationship between Xenocarida (Remipedia + Cephalocarida) and Hexapoda, and the underlying data and analyses are here critically discussed. Further, we present unpublished data from up to 27 nuclear, protein-coding genes (23kbp) for 58 taxa, representing most orders of non-endopterygote Hexapoda and expanding the arthropod data set to a total of up to 64 genes (42kbp) for 77 hexapods and 61 outgroup taxa. Maximum likelihood and Bayesian analyses of non-synonymous nucleotide substitutions robustly resolve most interordinal relationships. The resulting topology is congruent with those higher taxa that were well supported in previous studies, but provides additionally supported hypotheses for previously unresolved groupings. Particular attention is paid to the placement of Odonata and Ephemeroptera relative to Neoptera, of the 'living fossil' Tricholepidion gertschi to other Zygentoma, and to the phylogeny of Polyneoptera.

Phylogenetic relationships among superfamilies of Hymenoptera

Michael Sharkey[1], James Carpenter[2], Lars Vilhelmsen[3], John Heraty[4], Victoria Pook[5]

[1]University of Kentucky, U.S.A., [2]American Museum of Natural History, U.S.A., [3]Natural History Museum of Denmark, Denmark, [4]University of California, Riverside, U.S.A., [5]University of Kentucky, U.S.A.

The results of a large-scale analysis of the Hymenoptera, published in 2011 in Cladistics, are summarized. Representatives of all extant superfamilies, were scored for 392 morphological characters, and sequence data for four loci (18S, 28S, COI and EF-1a). Including three outgroup taxa, 111 terminals were analyzed. Well supported relationships include: Xyeloidea is monophyletic, Cephoidea is the sister group of Siricoidea + [Xiphydrioidea + (Orussoidea + Apocrita)]; Anaxyelidae is included in the Siricoidea, and together they are the sister group of Xiphydrioidea + (Orussoidea + Apocrita); Orussoidea is the sister group of Apocrita, Apocrita is monophyletic; Evanioidea is monophyletic; Aculeata is the sister group of Evanioidea; Proctotrupomorpha is monophyletic; Ichneumonoidea is the sister group of Proctotrupomorpha; Platygastroidea is sister group to Cynipoidea, and together they are sister group to the remaining Proctotrupomorpha; Proctotrupoidea s. str. is monophyletic; Mymarommatoidea is the sister group of Chalcidoidea; Mymarommatoidea + Chalcidoidea + Diaprioidea is monophyletic. Weakly supported relationships include: Stephanoidea is the sister group of the remaining Apocrita; Diaprioidea is monophyletic; Ceraphronoidea is the sister group of Megalyroidea, which together form the sister group of [Trigonaloidea (Aculeata + Evanioidea)]. Aside from paraphyly of Vespoidea within Aculeata, an expected result, all currently recognized superfamilies are supported as monophyletic. The diapriid subfamily Ismarinae is raised to family status, Ismaridae stat. nov. The support for these relationships will be discussed and areas of uncertainty will be highlighted

Phylogeny of the Chalcidoidea: Latest results and implications

John Heraty
University of California, Riverside, U.S.A.

Chalcidoidea represent one of the greatest radiations of insects. More than 500,000 species have been estimated although only about 23,000 species have been described. The morphological diversity of the group is extreme, and there are many issues with classification of the approximately 85 subfamiles and 19 families of insects. Results are presented for a molecular analysis of 720 taxa based on an analysis of 18S and 28S gene regions, and a combined morphological analysis of 300 taxa. Morphology was scored for 232 characters using an online character coding system and a collaborative network of researchers. The combined results provide the first robust phylogeny of the Chalcidoidea and allow for a better approach to the understanding of various attributes including the evolution of heteronomy, photoplay, sternorryhncan parasitism, planidial larvae and other attributes.

The first phylogenetic analysis based on combined morphological and molecular data for all families of Aculeata is presented. The morphological characters are modified from those used in previous studies by the authors, and are scored for more than 80 species terminals; they consist of 232 variables. The molecular data are from four genes (16S, 18S, 28S and COI), and comprise more than 3400 sites. Cladistic analysis using ichneumonoid outgroups resolves Chrysidoidea as monophyletic and the sister group of Apoidea and Vespoidea (that is, Aculeata s. str. is supported). Apoidea and Vespoidea are each monophyletic, and most families with multiple representatives are supported as monophyletic. The detailed results will be presented.

Evolution of the hymenopteran ovipositor system: Implications for host exploitation

Donald L. J. Quicke
Imperial College London and Natural History Museum, United Kingdom

Members of the order Hymenoptera tend to display considerable care in the placement of their eggs, be they phytophagous, parasitoids or predatory aculeates, and nearly always, the process of oviposition is accompanied by the deposition of various venoms and marking chemicals. This is achieved using the ovipositor and associated glands, which while being derived from the same basic structures throughout the order, display an enormous range of variation. The diversity of the ovipositor has enabled wasps to exploit a wide range of hosts, from eggs to adult insects, either exposed or deeply concealed. In this presentation I shall describe some of he many adaptive trends in hymenopteran ovipositors and show how they have both facilitated diversification and, in some cases, posed limitations on biological transitions.

Evolution of endoparasitism-strategies for dealing with the host milieu

Michael R. Strand
University of Georgia, U.S.A.

Parasitoid wasps have evolved a wide spectrum of developmental interactions with hosts. Here I synthesize and interpret results from the phylogenetic, ecological, physiological and molecular literature to identify factors that have influenced the evolution of endoparasitism. I first summarize major developmental strategies and assess the inventory of physiological and molecular traits that endoparasitoids use to successfully exploit hosts. I then discuss how certain traits have independently evolved in different lineages in likely response to similar host environments. Finally, I use a few specific examples to illustrate how phylogenetic, developmental and comparative genomic data can be used together to understand how some highly derived forms of endoparasitic development potentially evolved.

Host switching as biological transitions among parasitoids - exploiting spiders as a resource

Andrew D. Austin
The University of Adelaide, Australia

Spiders, their juvenile stages and eggs are utilised as prey/hosts by numerous insect groups, but particularly the Hymenoptera. Wasps attack spiders and their eggs as ecto- and endoparasitoids, or collect juvenile stages or adults as prey for their developing larvae, usually paralysing the spider and placing it within a nest or cell. Clearly, exploitation of spiders has evolved multiple times across the order, having been recorded by from four apocritan superfamilies and at least eight families. Of these the most diverse species radiations are found within the Platygastridae s.l. (as egg endoparasitoids) and Pompilidae (as juvenile/adult ectoparasitoids). With the recent advent of more robust phylogenies for hymenopteran families and genera it is possible to more accurately track the evolutionary transitions from utilising insect hosts to exploiting the various life history stages of spiders. Evident from this analysis is that there have been multiple independent switches to spider hosts/prey in all but one family, the Pompilidae, where exploiting spiders is an obligate family level trait. Further, where the biology of sister lineages is known two traits are implicated in the transition to utilising spiders, 1) the recognition of silk as a host-associated substrate (e.g. within the Platygastridae and Ichneumonidae) and 2) host searching within a specific habitat where several potential host/prey groups are found (e.g. Sphecidae). Possibly one of the most intriguing switches is found within the Pompilidae, where the ground-plan biology appears to be predation on spider eggs with a single switch to utilising juveniles/adults as prey for their larvae.

Evolution of sex determination and endosymbionts in the Hymenoptera

Leo W Beukeboom[1], Elzemiek Geuverink[2], Wen-Juan Ma[3], Louis van de Zande[4]

[1]University of Groningen, Netherlands, [2]University of Groningen, Netherlands, [3]University of Groningen, Netherlands, [4]University of Groningen, Netherlands

Sex determining mechanisms are bewildering diverse and turn over rapidly in evolution. Sex determination in insects occurs through a cascade of genetic switches with conserved genes at the bottom but strong diversification in the primary signal genes. I will discuss the genetic regulation and phylogenetic pattern of sex determination in the insect order Hymenoptera. All hymenopterans have haplodiploid reproduction (haploid males from unfertilised eggs, diploid females from fertilised eggs), but with different underlying genetic pathways of sex determination. Single locus complementary sex determination (slCSD) is known from >60 species in different families including Apoidea, Vespoidea and Ichneumonoidea. Within the family Braconidae slCSD and multi-locus CSD occurs in closely related species. Maternal effect genomic imprinting sex determination is only known from the chalcidoid Nasonia. Endosymbionts that alter their host reproduction and sex allocation occur widespread among Hymenoptera. They can induce cytoplasmic incompatibility, parthenogenesis, son killing and feminization. Their phylogenetic distribution is at least partially determined by the mode of sex determination. Recent evidence suggest that endosymbionts may directly manipulate the genetic cascade of sex determination.

Defensive mutualisms and diffuse host-symbiont co-evolution in Hymenoptera

Martin Kaltenpoth[1], Tobias Engl[2]
[1]Max Planck Institute for Chemical Ecology, Germany, [2]Max Planck Institute for Chemical Ecology, Germany

In all stages of their life cycle, insects are threatened by predators, parasites, and pathogens. The lifestyles and feeding ecologies of some hymenopteran taxa render them especially vulnerable to pathogen infestation. Specifically, the development in subterranean brood cells, mass provisioning of resources for the offspring, and the living together of social insects in large communities can enhance the risk of pathogen infestation and/or the spread of disease among conspecifics. In addition to the host's own defenses, some Hymenoptera have evolved symbiotic associations with protective microorganisms. Here, we will give an overview on such defensive mutualisms in solitary and social Hymenoptera and discuss their evolutionary histories based primarily on the two best-studied model systems: the symbioses of antibiotic-producing Actinobacteria with leaf-cutter ants and solitary digger wasps, respectively. Pseudonocardia and Streptomyces bacteria associated with leaf-cutter ants protect the host's nutritional resources by inhibiting the growth of a parasitic fungus that can otherwise infect and overgrow the ants' cultivar fungus. Similarly, in digger wasps of the tribe Philanthini, individual Streptomyces strains produce a complex cocktail of at least nine different antibiotics on the wasps' cocoons, which provide protection against a wide range of opportunistic fungal pathogens. Phylogenetic analyses of both symbiotic associations reveal a complex pattern of diffuse host-symbiont co-evolution, with repeated uptake of novel symbionts from the environment (leaf-cutter ants) or horizontal transfer of symbionts among host species (digger wasps). Evidently, defensive symbiotic interactions can remain stable over long evolutionary timescales in the absence of strict vertical symbiont transmission and host-symbiont co-diversification.

Tracing the rise of ants

Andrea Lucky[1], Michelle Trautwein[2], Benoit Guenard[3], Michael Weiser[4], Robert Dunn[5]

[1]University of Florida, U.S.A., [2]North Carolina State University, U.S.A., [3]North Carolina State University, U.S.A., [4]North Carolina State University, U.S.A., [5]North Carolina State University, U.S.A.

The evolution of the ants is increasingly well-understood due to recent analyses of phylogeny, divergence times and diversification rates. Yet leading hypotheses regarding the ancestral habitat of ants conflict with new findings that early ant lineages are cryptic and subterranean. Where the ants evolved, in respect to habitat, and how habitat shifts took place over time have not been formally tested. Here we reconstruct the habitat transitions of ants (Hymenoptera: Formicidae) through time, focusing on where they nest and forage (in the canopy, litter, or soil). We show that in contrast to the current consensus based on verbal arguments that ants evolved in tropical leaf litter, the ancestral stratum of all ants appears to be the soil with subsequent movement up into the litter and, in some cases, into the canopy. Given the global importance of ants, because of their diversity, ecological influence and status as the most successful eusocial lineage on earth, understanding the early evolution of this lineage has profound implications for understanding the factors that made this group so successful today.

Uncovering the evolutionary history of a unique family of ant parasitoids (Eucharitidae: Hymenoptera)

Elizabeth Murray[1], John Heraty[2]
[1]*University of California Riverside, U.S.A.*, [2]*University of California Riverside, U.S.A.*

Eucharitidae (Hymenoptera) is unique in that it is the sole insect family comprised of only ant parasitoids. Eucharitid wasps are found worldwide, composed of 53 genera and potentially 700+ species. They are known to attack the immature stages of five subfamilies of ants, and have been found to be prevalent parasitoids among some important ant groups. Morphology, molecules, and shared life history traits unite the Eucharitidae as monophyletic. We present a fossil-calibrated molecular phylogeny (18S, 28S-D2-D5, COI, and COII) based on a dataset of over 350 taxa from the Eucharitidae and its sister group, the Perilampidae. Patterns of host ant use will be examined in consideration of the most recent eucharitid phylogeny and the updated formicid phylogenies. Statistical analyses include estimating diversification rate shifts within eucharitids, the ancestral state reconstruction of ant hosts, and cophylogeny reconstruction of the host-parasitoid phylogenies. We introduce a revised hypothesis of the correlation between the phylogenetic relationships of parasitoid and host. Estimates from molecular divergence dating studies suggest an origin of Eucharitidae at roughly 65-75 mya, while major ant lineages diverged much earlier, well over 100 mya. Eucharitids display phylogenetic conservatism of ant hosts at the subfamily level, but the current pattern of lower-level host associations in Eucharitidae is best explained by host-switching and colonization throughout much of its evolutionary history. There may well be coevolution between the two hymenopteran groups due to the intimacy of the association.

Morphology and phylogeny of the enigmatic wasp genus Cales (Chalcidoidea: Calesinae)

Jason Mottern[1], John Heraty[2]
[1]*University of California, Riverside, U.S.A.*, [2]*University of California, Riverside, U.S.A.*

The hymenopteran superfamily Chalcidoidea currently contains about 22,000 described species in 19 families, with estimates of total species ranging from 100,000 to 500,000 worldwide. Despite the importance of many species as biological control agents, the species-level diversity and phylogenetic relationships within the group are poorly understood. The family Aphelinidae is among the chalcidoid groups most in need of systematic attention. These are small wasps ranging from 0.5 to 2.5 mm total body length that are mostly parasitoids of sternorrhynchus Hemiptera. This work will address species-level relationships within the unusual genus Cales, which has historically been associated with Aphelinidae, but is of questionable taxonomic position at this time. The phylogenetic placement of Cales within Chalcidoidea is uncertain, and is currently unplaced within Chalcidoidea. Molecular studies suggest that Cales is a distinct group unrelated to other Aphelinidae, though analyses have thus far failed to identify a well-supported sister-group relationship. There is currently one described species from the new world, Cales noacki, which has been introduced and established in citrus-growing regions of North America and Mediterranean countries, and has been relatively successful in reducing woolly whitefly populations. However, molecular analyses presented here suggest that many genetically distinct variants of C. noacki are present within its biological control and native ranges. These genetic variants appear to be morphologically indistinguishable, though detailed morphometric analyses are needed. Issues with taxonomic descriptions of cryptic species complexes are discussed.

Arthropod aloft: The origins of aerial behavior and flight

Robert Dudley
University of California, Berkeley, U.S.A.

Diverse insect taxa exhibit remarkable aerial capacities, including jumping, mid-air righting, parachuting, gliding, landing, controlled maneuvers, and flapping flight. The origin of flapping wings in hexapods greatly facilitated subsequent diversification, but both the paleobiological context and possible selective pressures for the evolution of wings remain contentious. Larvae of various arboreal hemimetabolous insects, as well as many adult canopy ants, demonstrate the capacity for directed aerial descent in the absence of wings. Aerial control in the ancestrally wingless archaeognathans suggests that flight behavior preceded the origins of wings in hexapods. In evolutionary terms, the use of winglets and partial wings to effect aerial righting and maneuvers could select for enhanced appendicular motions, and ultimately lead to powered flight. Flight behaviors that involve neither flapping nor wings are likely to be much more widespread than is currently recognized. Further characterization of the sensory and biomechanical mechanisms used by these aerially capable taxa can potentially assist in reconstruction of ancestral winged morphologies and facilitate our understanding of the origins of flight.

Multimodal sensory control of insect flight

Sanjay Prafullachandra Sane[1], Anand Krishnan[2], Sunil Prabhakar[3], Tanvi Deora[4], Harshada Hemant Sant[5], Umesh Mohan[6]

[1]National Centre for Biological Sciences, India, [2]National Centre for Biological Sciences, India, [3]National Centre for Biological Sciences, India, [4]National Centre for Biological Sciences, India, [5]National Centre for Biological Sciences, India, [6]National Centre for Biological Sciences, India

Insects use diverse sensory modalities including vision and mechanosensation to control flight in the rapid timescales. Sensory information transduced by various sensory organs is integrated within the brain which processes these diverse inputs and generates appropriate motor outputs to maintain stable flight. The chain of events from sensory perception to its processing and motor control must often happen within very short time scales, and hence presents a challenge to the insect nervous system. We have recently been exploring the mechanisms by which insects use multimodal sensory inputs to control their flight. Specifically, I will discuss two cases studies investigating the mechanosensory control of flight. In the first case study, I will describe how the antennae of moths (and other four-winged insects) provide mechanosensory cues that are critical for flight control. Here, I will describe the neural mechanisms that underlie the antennal control of flight, as well as the fine positioning of the antenna during flight. Furthermore, these inputs are strongly influenced by visual feedback. In the second case study, I will describe how the kinematics of wings and halteres of Dipteran insects remain in tight coordination in spite of the fact that their wing beat frequencies can often be on the order of a few hundred per second. Together, these studies shed some light on how insect morphologies and their sensory structures have evolved to meet the challenges of providing rapid sensory feedback during flight.

Dynamic flight stability of a bumblebee in forward flight

Mao Sun
Beijing University of Aeronautics & Astronautics, China

The longitudinal dynamic flight stability of a bumblebee in forward flight is studied. The method of computational fluid dynamics is used to compute the aerodynamic derivatives and the techniques of eigenvalue and eigenvector analysis are employed for solving the equations of motion. The primary findings are following. The forward flight of the bumblebee is not dynamically stable due to the existence of one (or two) unstable or approximately neutrally stable natural modes of motion. At hovering to medium flight speed (flight speed U=0-3.5 m/s; advance ratio J=0-0.44), the flight is weakly unstable or approximately neutrally stable; at high speed (U=4.5 m/s; J=0.57), the flight becomes strongly unstable (initial disturbance double its value in only 3.5 wingbeats).

Ecophysiology of migratory flight in Lepidoptera

Jeremy N. McNeil
Western University, Canada

Juvenile hormone is an important determinant in the response of migratory insects to predictable or unpredictable deterioration of habitat quality. Low titers, produced in response to cues indicating a decline in habitat quality, stimulate migratory behaviour while under favourable conditions high JH titers initiate reproductive maturation. However, it is still not entirely clear if sexual maturation only occurs once migratory flight has terminated or whether it may occur during the migratory process. If, as suggested from recent results obtained with Mythimna separata, reproductively active individuals migrate, then the costs associated with continuous long distance flight on future reproductive output may differ between immature and sexually mature individuals. In this talk I will discuss adaptations that may reduce these costs and the importance of using individuals reared under field conditions, on natural diets, to address these questions experimentally.

Reproductive benefits of seasonal insect migration to high latitudes

Jason Chapman
Rothamsted Research, United Kingdom

Billions of insects migrate between winter and summer ranges to take advantage of seasonally-available breeding resources. To cover the distances required (hundreds of kilometers), many insects rely on wind assistance, and routinely ascend hundreds of meters above the ground to migrate in fast-moving airstreams. Given that wind speeds are typically three to five times faster that the insects' airspeeds, it was not clear what influence high-flying migrants could exert on their migration direction or whether substantial 'return' migrations to lower-latitude winter-breeding areas were possible. To answer this question, I have studied the flight behavior and migration patterns of large nocturnal moths (including Autographa gamma and Noctua pronuba) in Europe with specialized entomological radars. Radar observations demonstrated that an ability to select favorably-directed airstreams (i.e. northwards in spring and southwards in autumn) is widespread among high-flying migrant Lepidoptera, and thus the migrants gained considerable wind assistance for their seasonal migrations. Furthermore, moths preferentially fly at the altitude of the fastest winds, and partially compensated for wind drift away from their seasonally-preferred migration directions. Trajectory simulations show that these flight behaviors result in significant increases in mean nightly migration distance, and a high degree of success in reaching the next breeding region, while population monitoring indicated that high-latitude summer-breeding results in a fourfold population increase. The migration strategies employed by the study species explain how such small, short-lived and relatively slow-flying organisms are able to cover such great distances in seasonally-beneficial directions, and demonstrate that migration is highly adaptive in such cases.

Orthopteran mass migrations

Gregory A. Sword
Texas A&M University, U.S.A.

Orthopterans such as swarming locusts and Mormon crickets provide some of the most spectacular examples of insect mass migration. Swarms can contain billions of individuals, and in the case of flying adult locusts, are capable of extended flights across continents and oceans. These insect mass movements have been noted by humans throughout history, in no small part due to their ecological and cultural impact as agricultural pests. However, our understanding of the proximate and ultimate mechanisms underlying swarm formation and movement has changed dramatically in a relatively short amount of time. I will provide an overview of these advances, highlighting recent findings across disciplines ranging from radiotelemetry and molecular population genetics to collective dynamics and nutritional ecology.

Orientation behaviour of nocturnal insect migrants observed with a monitoring radar

Vincent Alistair Drake[1], Haikou Wang[2]
[1]*University of New South Wales and University of Canberra, Australia,* [2]*Australian Plague Locust Commission, Australia*

Nocturnal insect migration over the extensive inland plain of southeastern Australia has been observed over several seasons with an Insect Monitoring Radar (IMR) located at Bourke, New South Wales. The species detected are primarily Australian plague locusts, Chortoicetes terminifera, and a variety of moths (mostly Noctuidae). Directed movements involving numerous individuals ? i.e. migrations ? are frequently detected between August (early spring) and April (mid-autumn). For these nights, the number of targets providing good-quality echo signals, i.e. signals from which all trajectory and target-character parameters can be retrieved, is in the low thousands. This allows examination of sample variances and of variations with height and time of night, and sometimes also comparison of the simultaneous behaviours of different migrant types. The radar observations show that a degree of common orientation is almost invariably present in the stable atmospheric conditions in which nocturnal insect migration typically occurs, but that the range of orientation angles is often broad. Mean orientations vary with both height and time, and these changes appear to be associated with changes in the movement directions of the insects, with these in turn being determined primarily by the wind. However, there is often an offset between the orientation and movement directions, and this offset seems to vary with the movement direction. With migrations occurring in all directions at this site (in the warmer months), and more than one target type quite often present, a careful analysis may eventually reveal the cues and processes producing the orientation phenomena observed there.

Orientation and layering behaviors of nocturnal migrant insects revealed with entomological radar in northern China

Honggiang Feng[1], Kongming Wu[2]
[1]*Henan Academy of Agricultural Sciences, China,* [2]*Chinese Academy of Agricultural Sciences, China*

The high altitude migrations of nocturnal migrant insects over both continent and sea have been observed with entomological radar and light traps in the past decade in northern China. The insects being observed include beet armyworm Spodoptera exigua, beet webworm Loxostege sticticalis, cotton bollworm Helicoverpa armigera, oriental armyworm Mythimna separata, dragonflies Pantala flavescens and ground beetles Pseudoophonus griseus. Orientation and layering were the two most attractive behaviors of these nocturnal migrants. Migrant insects tended to heading towards the northeast during spring migration, but southwest during autumn migration, with a general pattern of heading downwind. Some strong migrants could sometimes head across the wind or even upwind. Other less strong migrants, such as H. armigera, headed towards the southwest in varied downwind directions during autumn. The M. separata was used to study the possible mechanisms of orientation during migration with a tethered flight simulator. It could orient toward northeast in spring but southwest in autumn without the cues of winds and lights, which indicated M. separata might have used the geographic magnetic field as the cues for orientation. Layering was a complicated behavior and might be a integrated reaction to temperature, wind speed and wind direction through space (vertical profile) and time (season). A simple model basing on statistics has been built up to simulate the layering behavior. Apparently, more elaborated experiments and sophisticated statistics were desired to explore the mechanism of orientation and layering behaviors in nocturnal migrants.

Radar entomology in Japan

Akira Otuka[1], Toshiaki Takano[2], Yuta Matsumoto[3], Masaya Matsumura[4]
[1]NARO/Kyushu Okinawa Agricultural Research Center, Japan, [2]Chiba University, Japan, [3]Chiba University, Japan, [4]NARO/Kyushu Okinawa Agricultural Research Center, Japan

Many long-distance migratory insects come into Japan. Among them, rice planthoppers are important insect pests of rice. To know the timing and area of their immigrations in advance, a migration prediction method has been developed. A real-time prediction system using the method is now operational and the information is delivered to plant protection officers. Its simulation model employs the knowledge on the insect flight unveiled by an entomological radar in 1980s. To improve the prediction accuracy, it is necessary to approach real images of immigrants in flight over western Japan, such as their aerial density at altitudes and an unknown landing process. It is then to feed back the information to modification of the model. Currently we have two types of entomological radar: one is a Vertical Looking Radar-type in x-band, the other a 95 GHz FMCW-type millimetric radar. The former targets middle-sized moths, and is currently under construction. The latter targets small-sized insects, and was tested during a wheat harvesting season in early summer, 2011. Its observation was compared with the monitoring data by a net trap dangled under a balloon. Many target echoes were observed in daytime and at dusk on sunny days, but a small number at dawn and in early morning, and few in night time. The aerial density of echoes was estimated and found to be comparable to that of the net trap monitoring. The size of echoes estimated by a spherical water droplet approximation ranged from 1 to 0.2 mm.

The role of FoxO in integrating insulin and ecdysone signaling during body size regulation

Takashi Koyama[1], Christen K Mirth[2]
[1]*Instituto Gulbenkian de Ciencia, Portugal,* [2]*Instituto Gulbenkian de Ciencia, Portugal*

Body size regulation, a conspicuous and fundamental process in any organism, is best understood in insects. In the fruit fly Drosophila melanogaster, larvae regulate their final body size by controlling both growth rate, through insulin/insulin-like growth factor signaling (IIS) and target of rapamycin signaling, and regulating the duration of the growth period, via the steroid hormone ecdysone. Recent studies have shown that these two processes interact; IIS stimulates ecdysone synthesis from the prothoracic gland by up-regulating ecdysone biosynthesis genes. How this occurs is still unclear. In mammalian and nematode cells, the IIS modulates steroid hormone signaling through the interaction between a downstream component of the IIS, forkhead box type O (FoxO), and nuclear hormone receptor superfamily members. Given this, we have found that a heterodimeric partner of Ecdysone Receptor, Ultraspiracle (Usp), binds to FoxO. Furthermore, we found that overexpression of FoxO RNAi in the prothoracic gland (PG) induces premature patterning of the imaginal discs in early third instar larvae fed on sucrose alone, suggesting ecdysone synthesis occurs prematurely. This FoxO/Usp association occurs independently of 20-hydroxyecdysone, suggesting that the complex may potentially regulate ecdysone signaling in a nutrient-dependent, but ecdysone-independent manner. To explore the function of FoxO/Usp complex, we have created two different types of transgenes that inhibit the formation of FoxO/Usp complexes without disrupting independent transcriptional activity of FoxO. We will discuss about the function of the FoxO/Usp complex on growth period determination.

The function of Rab4b in insect growth and development

Li Hou[1], Mei-Juan Cai[2], Qian Song[3], Jin-Xing Wang[4], Xiao-Fan Zhao[5]
[1]Shandong University, China, [2]Shandong University, China, [3]Shandong University, China, [4]Shandong University, China, [5]Shandong University, China

The insulin and 20-hydroxyecdysone (20E) pathways coordinately regulate insect growth and metamorphosis. However, the molecular mechanism of the interaction of these two pathways in regulating insect development is not well understood. In the present study, we found that a small GTPase Rab4b from a lepidopteran insect Helicoverpa armigera participates in signal transduction in the two pathways. The results show that RNA interference of Rab4b in larvae results in larval death, abnormal metamorphic transition or small pupae, and the decrease of glycogen levels. The molecular mechanisms were demonstrated that knockdown of Rab4b in the larvae suppresses the transcription of glycogen synthase (GS), as well as the metamorphic-initiating factor (Br) and hormone receptor 3 (HR3), but increases the transcription of Forkhead box class O (FOXO). Further studies in the cell line confirm that Rab4b is necessary for gene transcription in the insulin and 20E pathways. Rab4b locates in the cytoplasm and keeps FOXO in the cytoplasm in the insulin pathway, but travels toward the cell membrane upon 20E induction without affecting the FOXO location. The transcription of Rab4b could be upregulated by insulin injection or glucose feeding to the larvae, but not by 20E or juvenile hormone analogy methoprene. Our data suggest that Rab4b plays roles in insect growth and metamorphosis by regulating glycogen synthesis gene transcription in the insulin and 20E pathways. This work was supported by the grants from the National Natural Science Foundation of China (No. 30970404) and National Basic Research Program of China (973 Program, 2012CB114101).

Balancing crosstalk between steroid-induced autophagy and apoptosis in *Drosophila* remodeling fat body

Hanhan Liu[1], Sheng Li[2]
[1]*Shanghai Institutes for Biological Sciences, China,* [2]*Shanghai Institutes for Biological Sciences, China*

Apoptosis and autophagy, two types of programmed cell death (PCD), play critical roles during development in animals. Common stimuli can induce combined autophagy and apoptosis; in many instances, the two PCD processes antagonize each other and develop in a mutually exclusively manner. In this study, we discovered that during the larval-pupal transition in Drosophila, a balancing crosstalk occurs between autophagy and apoptosis in the remodeling fat body: the inhibition of autophagy induces apoptosis and the inhibition of apoptosis induces autophagy. Both PCD processes are induced by the steroid hormone, 20-hydroxyecdysone (20E), via its nuclear receptor, EcR-USP. E93, a 20E primary-response gene encoding a HTH transcription factor, plays a predominant role in coordinating 20E-induced PCD, mainly because E93 upregulates the genes responsible for both autophagy and apoptosis and inhibits the PI3K-TORC1 signaling. The Drosophila remodeling fat body provides an in vivo model for understanding the molecular mechanism of the balancing crosstalk between autophagy and apoptosis, which are induced by 20E and coordinately mediated by E93.

Mechanisms and evolution of nutrient-dependent horn allometry in beetles

Laura Corley Lavine[1], Douglas J. Emlen[2], Ian A. Warren[3], Hiroki Gotoh[4], Ian Dworkin[5], Toru Miura[6]

[1]Washington State University, U.S.A., [2]University of Montana, U.S.A., [3]Washington State University, U.S.A., [4]Washington State University, U.S.A., [5]Michigan State University, U.S.A., [6]Hokkaido University, U.S.A.

Our research focuses on the genetic mechanisms of conditional-expression and trait exaggeration in weapons of sexual selection. We study these mechanisms of weapon growth in three different lineages of scarab beetles, encompassing the three principle origins of exaggerated weapons of sexual selection in this superfamily: horns of dung beetles (Scarabaeinae) and rhinoceros beetles (Dynastinae), and mandibles of stag beetles (Lucanidae). In the process, we have developed genomic tools and resources for all three lineages. By examining how traits grow to extreme proportions, we have begun to elucidate the underlying physiological and genetic pathways regulating the rate of trait growth, and coupling growth with environmental factors such as nutrition and with individual body condition. We have focused on insulin and insulin-like growth factors because they have been shown to be essential for regulating tissue growth and body size and because their role has been largely conserved among metazoans. We predicted that increased cellular sensitivity to the insulin/IGF pathway within specific trait primordia might be a mechanism for the evolution of disproportionate, or exaggerated, growth in the showy ornaments and weapons of sexual selection. Here, we present results from our studies of the insulin receptor in the rhinoceros beetle and stag beetle which support the hypothesis that the insulin/IGF pathway contributes to exaggerated growth of animal weapons.

The regulation of organ allometry in *Drosophila*

Alexander Shingleton[1], Huiyuan Tang[2], Yu Liang[3], R. Craig Stillwell[4], Ian Dworkin[5], Peter Bates[6], W. Anthony Frankino[7]
[1]Michigan State University, U.S.A., [2]Michigan State University, U.S.A., [3]Michigan State University, U.S.A., [4]Michigan State University, U.S.A., [5]Michigan State University, U.S.A., [6]Michigan State University, U.S.A., [7]University of Houston, U.S.A.

Morphological diversity between species is dominated by variation in body proportion; that is the size of individual organs relative to the size of the body as a whole. Nevertheless, we have a very poor understanding of how body proportion is regulated developmentally and how this regulation evolves. Using Drosophila as a model organism, we identify the developmental mechanisms that control how organ size scales with body size, that is organ allometry. These mechanisms control morphological scaling and body proportion by regulating the extent to which body and organ size respond to environmental, and likely genetic, variation. We use mathematical modeling to explore how evolution may act on these mechanisms to alter scaling relationships . Finally, we show how artificial selection can target these mechanisms and alter the allometric relationship between organ and body size in Drosophila.

Is internal hypoxia a signal for the transition from growth to molting in insect larvae?

Jon Fewell Harrison[1], Vivian Callier[2]
[1]*Arizona State University, U.S.A.,* [2]*Arizona State University, U.S.A.*

Body size profoundly affects many aspects of animal biology, yet the mechanisms responsible for determining the size of animals remains one of the fundamental unsolved problems of developmental biology. Insects and other arthropods add substantial mass and oxygen need within each larval instar, while many aspects of the tracheal respiratory system remain fixed in size. Thus sensing of reduced internal PO2 could be one mechanism that leads to cessation of larval growth and initiation of the molting cascade, which occurs when the larva attains a critical weight. Metabolic rates of third instar Manduca sexta and Drosophila melanogaster larvae increase linearly with mass before the critical weight, and remain constant as mass increases after the critical weight, supporting the concept of oxygen-limitation later in the instar. Rearing in hypoxia causes a dose-dependent decrease in adult size in mostinsects, consistent with the hypothesis that oxygen-limitation in the final instar determines the size at which metamorphosis is initiated, and therefore the final body size.Hypoxic exposure during the third larval instar reduces feeding rate, with a consequent effect on growth rate. Hypoxic rearing shifts the critical weight to a smaller size, consistent with hypoxic-regulation of development. Despite the smaller critical weight, hypoxia delays pupariation. Late-third instar larvae grown in normoxiashow elevated levels of hypoxia-inducible factor (HIF) signaling, suggesting that HIF-signaling of reduced PO2 levels could be a component of the signaling pathway that reduces larval feeding, growth and critical weight, and promotes transition to molting and adult size determination.

Hemolymph protease cascades in immune responses of *Manduca sexta*

Michael R Kanost[1], Chunju An[2], Jayne M Christen[3], Yang Wang[4], Haobo Jiang[5]

[1]Kansas State University, U.S.A., [2]China Agricultural University, China, [3]Kansas State University, U.S.A., [4]Oklahoma State University, U.S.A., [5]Oklahoma State University, U.S.A.

Extracellular serine protease cascades mediate rapid responses to infection and wounding in animals. Such cascade pathways offer mechanisms for rapid, local amplification of a small initial signal, with potential for regulation at multiple levels. The proteases circulate as inactive zymogens and become sequentially activated upon recognition of aberrant tissues or microbial polysaccharides. After accomplishing their functions, the active enzymes are often inactivated by serine protease inhibitors. It is becoming apparent that protease cascade pathways in blood are often connected, creating protease "webs," and this is likely to be true in Manduca sexta and other insect species. Activation of serine proteases in hemolymph is a component of several types of lepidopteran immune responses, including melanotic encapsulation, activation of antimicrobial peptide synthesis, and modulation of hemocyte function. Many insect hemolymph serine proteases are composed of a carboxyl-terminal protease domain and an amino-terminal clip domain. Clip domains are 35-55 amino acid residue sequences that may mediate interactions of members of protease cascade pathways. We have cloned cDNAs for more than 20 clip domain proteases expressed in fat body or hemocytes of Manduca sexta and are investigating their functions in immune responses and their regulation by members of the serpin family of protease inhibitors. Hemolymph protease pathways leading to activation of prophenoloxidase and activation of the cytokine, spatzle, will be discussed, as well as regulation of these pathways by inhibitory serpins. Initial observations on hemolymph proteases and serpins from the Manduca sexta genome sequence will be provided. (supported by NIH grants GM41247 and GM58634)

Identification of bacterial genes expressed upon infection to control pathogenicity in *Drosophila*

Yoshinobu Nakanishi
Kanazawa University, Japan

Upon infection bacteria appear to adapt to the host environment by altering the pattern of gene expression. Most probably, host substances including those that constitute the host immune system induce this change in invading bacteria. To elucidate the mechanism of bacterial gene regulation and characterize newly expressed genes should deepen our understanding of the behavior of bacteria in host organisms as well as the state of infections diseases. To identify bacterial genes that are induced upon infection, we examined the level of expression of Escherichia coli genes coding for proteins that control gene expression, i.e. sigma subunits of RNA polymerase and proteins involved in the two-component sensor-transducer response system, in Drosophila melanogaster that had been abdominally injected with E. coli. We then determined survival ratios of adult flies after abdominal infection with E. coli that harbor mutations in the genes identified. We found that many E. coli mutants showed altered levels of pathogenicity compared to their parental strain, indicating that sigma subunits and two-component systems are involved in the control of pathogenicity of E. coli to Drosophila. These proteins are presumed to induce transcription of a set of genes leading to the production of pathogenicity-related proteins. This is most likely a bacterial strategy for adaptation to the host environment to achieve persistency in host organisms coping with immune reactions. It is probable that bacteria change the pattern of gene expression when exposed to host substances, hemolymph proteins in particular, but precise mechanisms await further investigation.

Immune proteins in hemolymph of *Galleria mellonella*

In Hee Lee
Hoseo University, Republic of Korea

Galleria mellonella (Greater wax moth) might be one of appropriate models in that it arms itself with a variety of hemolymph proteins to kill and eliminate invading microorganisms. Aside from prophenoloxidase (PPO) system, there are at least five types of immune proteins in the hemolymph of G. mellonella. As is usual in most of insects, G. mellonella has a cecropin and a lysozyme as inducible antimicrobial proteins. Apolipophorin-III that is known to involve in the lipid metabolism might contribute to humoral and cellular immune reactions triggering in the hemolymph upon microbial invasion. In addition, a small protein (9.1 kDa), named GmCP8, was demonstrated to play a role as a multiligand receptor to detect diverse polysaccharides (LPS, LTA and beta-1,3-glucan) present in the microbial cell wall, thereby contributing substantially to phagocytosis of microorganisms by hemocytes. As the fifth immune protein found in the hemolymph of G. mellonella, Gm protein-24 was confirmed to be antimicrobial protein capable of killing gram-positive bacteria but not gram-negative bacteria. The protein has strong affinity to teichoic acid that is the outermost component of cell wall of gram-positive bacteria, showing anti-staphylococci activity. Intriguingly, it was shown that Gm protein-24 exerted its anti-staphylococci activity in a mode of action distinctly different from conventional antimicrobial peptide such as cecropin. Overall, a better understanding of immune proteins occurring in the hemolymph of G. mellonella might provide us with critical insight into the insect defense mechanisms.

Antiviral and "specific" immunity in a crustacean

Kenneth Tord Söderhäll
Uppsala University, Sweden

The circulating blood cells (hemocytes) are crucial for protecting invertebrates against invading microorganisms, and they are directly involved in recognition, phagocytosis, melanization and cytotoxic reactions. Many microorganisms trigger hemocyte synthesis and release from the HPT, and this may be one way for the host to respond to an infection. Therefore we have studied hematopoiesis intensely and have now in detail deciphered the molecular mechanisms in hematopoietic stem cell proliferation and differentiation. Recently we have cloned Dscam proteins from P. leniusculus. The Down syndrome cell adhesion molecule (Dscam) is a member of the immunoglobulin super family of proteins. Dscams are large proteins containing ten Ig domains and six fibronectin type III domains, and this structure is conserved across animal phyla. There are two Dscam genes in humans (DSCAM), and they have an essential role in neural wiring, in both vertebrate and insects. An intriguing difference in Dscam gene structure is the exon duplication in arthropods and which give rise to an array of alternative spliced isoforms in insects and crustaceans. Alternative splicing of individual exon sequences allows for expression of several thousands of isoforms . We have now shown that hemocytes that express different spliced isoforms are induced by specific challenge, and moreover that these specific forms are important in clearing bacteria. Finally we are also studying the antiviral response in crayfish and shrimp and found a new mechanism by which the White spot syndrome virus is able to replicate in the hemocytes.

A link coordinating humoral and cellular responses in *Drosophila* immunity

Shoichiro Kurata
Tohoku University, Japan

The fruit fly Drosophila melanogaster is an excellent model organism to decipher the basic principles of innate immune responses consisting with humoral and cellular responses. One of the humoral responses is induction of antimicrobial peptides (AMPs), that is controlled by two distinct innate immune signaling pathways, the Toll and immune deficiency (imd) pathways. The Toll pathway is mediated by Toll receptor and dMyD88 adaptor protein, the imd pathway is mediated by Imd adaptor protein. The cellular responses are mainly caused by blood cells called hemocytes. To identity genes capable of activating immune responses, we have established a genome wide gain-of-function genetic screen in Drosophila and identified peptidoglycan recognition protein -LE recognizing diaminopimeric acid-type peptidoglycans and activating imd-dependent AMP synthesis and autophagy (PNAS 2002, EMBO J. 2004, Nature Immunol. 2006, 2008). Here, using the genetic screen, we identified a receptor guanylyl cyclase (rGC). The rGC shows amino acid sequence similarity to mammalian receptor guanylyl cyclases producing cyclic GMP such as Atrial Natriuretic Peptide receptor. The rGC is involved in both Toll-independent/dMyD88-dependent humoral response and dMyD88-independent cellular response, that is crucial for host survival against Gram-positive bacterial infections but not against Gram-negative bacterial infections.

Hemolymph pattern recognition proteins involved in innate immune responses of *Tenebrio molitor*

Bok Luel Lee
Pusan Natl University, Republic of Korea

Innate immunity is a crucial host defense mechanism against microbial infection in all animals. The insect's Toll proteolytic signaling cascade is activated upon recognition of Gram-positive bacteria and fungi, resulting in the expression of antimicrobial peptides via NF-kappaB-like transcription factor. These innate immune responses are mediated by a serine protease cascade leading to the processing of pro-Spatzle, which generates the functional ligand of the Toll receptor. Recently, we analyzed the serine protease cascade regulating the Toll signaling pathway using larvae of the beetle, Tenebrio molitor. This large insect enabled us to collect large amount of hemolymph (the insect blood) allowing purification of serine proteases and pathogen recognition receptors. Our studies demonstrated that the recognition of bacterial Lys-type peptidoglycan (PG) by the PG recognition protein-SA (PGRP-SA)/Gram-negative binding protein 1 (GNBP1) complex activates pro-Spatzle via the sequential activation of three serine proteases: modular serine protease (MSP), Spatzle processing enzyme-activating enzyme (SAE) and Spatzle processing enzyme (SPE). Additionally, we provide biochemical evidences of how the Tenebrio PGRP-SA/GNBP 1 complex-mediated bacteria recognition signal is transferred to pro-Spatzle leading to the production of antimicrobial peptides. Injection of Lys-type PG into Tenebrio larvae induced production of two antimicrobial peptides, Tenecin 1 and Tenecin 2, which are also inducible by injection of the active form of processed Spatzle. Furthermore, we identified five different serpins that are involved in the regulation of Toll signaling cascade and melanin synthesis pathway. We also examined in vitro and in vivo biological functions of these serpins during Toll activation cascade.

Deploying the mosquito IMD pathway in the war against malaria

George Dimopoulos
Johns Hopkins University, Bloomberg School of Public Health, U.S.A.

A causative agent of human malaria, Plasmodium falciparum, is transmitted by Anopheles mosquitoes. The malaria parasite is under intensive attack from the mosquito's innate immune system during its sporogonic development. We have used genetic engineering to create immune-enhanced Anopheles stephensi mosquitoes through blood meal-inducible expression of a transgene encoding the IMD pathway-controlled NF-kB Rel2 transcription factor in the midgut and fat-body tissue. We have determined the anti-P. falciparum circuit of the IMD pathway and identified several pathway factors that could serve as tools for the development of genetically modified super-immune mosquitoes. Rel2 transgenic mosquitoes showed greater resistance to Plasmodium and microbial infection as a result of timely concerted tissue-specific immune attacks involving multiple effectors. The relatively weak impact of this genetic modification on mosquito fitness under laboratory conditions encourages further investigation of this approach for malaria control.

Biological functions of insect cytokine growth-blocking peptide (GBP)

Yoichi Hayakawa
Saga University, Japan

The expression of antimicrobial peptide genes (AMPs) is induced by septic injury under the control of the Toll and immune deficiency (Imd) pathways in Drosophila melanogaster, and Spatzle is the known insect cytokine that stimulates one of these pathways, Toll. Here we demonstrated that growth-blocking peptide (GBP) is also a potent cytokine that activates AMP expression in insects under various stress conditions. Injection of silkworm Bombyx mori GBP enhanced transcription of AMPs in B. mori larvae. To extend this finding to the Drosophila immune system, we identified Drosophila GBP through isolation and sequencing of the bluebottle fly Lucilia cuprina GBP. Overexpression of GBP in Drosophila larvae elevated expression of AMPs such as Metchnikowin and Diptericin in all tested tissues, fat body, hemocytes, and integuments. GBP-induced AMP expression in Drosophila larvae did not require orthodox Toll and Imd pathway-related genes such as spatzle, dorsal, Dorsal-related immune factor, peptidoglycan-recognition protein-LC (PGRP-LC), PGRP-LE, and Relish, but imd itself and basket were essential, indicating that this signaling is activated by association with the adaptor protein Imd to enhance AMP expression through the Jun N-terminal kinase pathway. RNAi knockdown of GBP expression prevented the bacterial challenge-induced AMP expression, and enhanced susceptibility to the bacteria. The enhancement of AMP expression by noninfectious stresses such as subcutaneous damage and temperature fluctuation was apparent in control larvae but not in GBP-knockdown larvae. These results indicate that the Drosophila GBP signaling pathway mediates acute innate immune reactions after various stress stimuli, regardless of whether they are infectious or noninfectious.

Both biogenic monoamine and PSP activate hemocyte-spreading via eicosanoids

Yonggyun Kim[1], David Stanley[2]
[1]*Andong National University, Republic of Korea,* [2]*USDA/Agricultural Research Service, U.S.A.*

Insect innate immunity is composed of humoral and hemocytic (or cellular) responses. Plasmatocyte spreading peptide (PSP), the first reported insect cytokine, is responsible for mediating the spreading and attachment of some sub-classes of plasmatocytes to nodules. Prostaglandins (PGs), one group of eicosanoids formed from arachidonic acid (AA), also mediate plasmatocyte spreading (PS), although the potential interactions between the PSP and PG signal transduction pathways have not been investigated. We tested our hypothesis that PSP acts via biosynthesis of eicosanoids, specifically PGs, in the beet armyworm, Spodoptera exigua. Here we report that PSP and PGE2 independently stimulated Ca++-dependent PS, that inhibitors of PG biosynthesis reversibly blocked PS, that dsRNA silencing the gene encoding proPSP blocked PS, which was rescued by PSP and by AA, that PSP-stimulated PS was reversibly impaired by inhibitors of PG biosynthesis, and the inhibitor-impaired spreading was rescued by AA. Taken together, these points strongly support our model showing that PSP acts via a plasmatocyte-surface receptor, which stimulates biosynthesis of the PGs responsible for mediating plasmatocytes spreading. In addition, biogenic monoamines, 5-hydroxytryptamine and octopamine, also activate hemocyte spreading behavior via eicosanoids. These studies suggest that eicosanoids are the end signaling molecules activating hemocyte behavior after cross-talks with other cytokines in response to pathogen infection.

Many insects eat the green leaves of plants but excrete black feces in a yet-unknown mechanism. Insects cannot avoid ingesting pathogens with food that will be specifically detected by the midgut immune system. However, just as in mammals, many pathogens can still escape the insect midgut immune system and arrive in the hindgut, where they are excreted out with the feces. Here we show that the melanization of hindgut content induced by prophenoloxidase, a key enzyme that induces the production of melanin around invaders and at wound sites, is the last line of immunity to clear bacteria before feces excretion. We used the silkworm Bombyx mori as a model and found that prophenoloxidase produced by hindgut cells and is secreted into the hindgut contents. Several experiments were done to clearly demonstrate that the blackening of the insect feces was due to activated phenoloxidase, which served to regulate the number of bacteria in the hindgut. Our analysis of the silkworm hindgut prophenoloxidase disclose the natural secret why the insect feces is black and provides insight into the hindgut innate immunity that is still rather unclear in mammals.

Is lebocin-like protein an antibacterial peptide that specifically functions in the midgut of *Spodoptera litura*?

Xingyu Lin[1], Sichun Zheng[2], Qili Feng[3]

[1]South China Normal University, China, [2]South China Normal University, China, [3]South China Normal University, China

Lebocin is one of pro-rich antimicrobial peptides found in several Lepidoptera insects. By expressed sequence tag (EST) analysis, we found that a lebocin gene was highly expressed, particularly in the prepupal midgut of Spodoptera litura. Two full-length S. litura lebocin cDNAs (Sllebocin 1 and 2) were cloned and they are 666 and 929 bp in length, encoding 35 and 33 amino acid residues, respectively. Transcripts of these two lebocins were detected in midgut, epidermis, fat body, hemocytes and Malpighian tubules. The expression levels of the genes were much higher in the prepupal, pupal and adult stages than in the larval stage. No expression was detected in the egg. As compared to the antimicrobial peptides attacin, cecropin, defensin gallerimycin and lysozyme, Sllebocin 2 had the highest levels of expression at the pupal stage. 20-hydroxyecdysone induced the expression of these two Sllebocin transcripts. Both Gram-positive and Gram-negative bacteria induced the expression of the S. lutura lebocins in 6th instar larvae. These results suggest that in addition to antibacterial activity, the lebocins might play an un-identified role in the midgut during larval?pupal metamorphosis. This project is supported by grants from the Chinese National Natural Science Foundation (31071981) and the National High-Tech Research and Development Program (2011AA10A204).

Drosophila immune responses against entomopathogenic nematodes

Ulrich Theopold[1], Zhi Wang[2], Pavel Dobes[3], Robert Markus[4], Pavel Hyrsl[5]

[1]Stockholm University, Sweden, [2]Stockholm University, Sweden, [3]Masaryk University, Czech Republic, [4]Stockholm University, Sweden, [5]Masaryk University, Czech Republic

Entomopathogenic nematodes (EPN's) of the genera Heterorhabditis are obligate and lethal insect parasites. In recent years they have been used increasingly as biological control agents. Infective juveniles occur free living in the soil and are capable of seeking out hosts and penetrate them through the cuticle or natural orifices. EPN's are symbiotically associated with bacteria of the genera Photorhabdus. The bacterial symbionts are essential to kill the host (within 24-48 hours) and digest host tissues. Drosophila larvae are more resistant to nematode infection than Galleria mellonella, but both can be used as natural infection model. The tripartite model (Drosophila, nematodes, bacteria) was recently established and used to show an immune function for transglutaminase, a conserved clotting factor. In this study we optimized the use of Drosophila as hosts and used different Drosophila mutants or RNAi lines with defects in clotting or other branches of the immune system. We demonstrated a protective function during nematode infection for known clotting substrates and for a phospholipase, while Toll an Imd immune pathways on their own are not required during nematode infection. The phenoloxidase cascade cooperates with clotting, but is not efficient again nematodes itself. In conclusion, we show that the Heterorhabditis/Photorhabdus infection model is suitable to identify novel regulators of innate immunity.

Cotesia congregata bracovirus (CcBV) induces apoptosis of parasitized host plasmatocytes

Germain Chevignon[1], Sebastien Moreau[2], Hubert Guimier[3], Elisabeth Huguet[4], Jean-Michel Drezen[5]

[1]Institut de Recherche sur la Biologie de l'Insecte CNRS, France, [2]Institut de Recherche sur la Biologie de l'Insecte CNRS, France, [3]Institut de Recherche sur la Biologie de l'Insecte CNRS, France, [4]Institut de Recherche sur la Biologie de l'Insecte CNRS, France, [5]Institut de Recherche sur la Biologie de l'Insecte CNRS, France

Cotesia congregata (Hymenoptera: Braconidae) develops as a gregarious endoparasitoid into larvae of the tobacco hornworm Manduca sexta (Lepidoptera: Sphingidae). The parasitoid wasp has evolved strategies of virulence using a viral obligatory symbiont, Cotesia congregata bracovirus (CcBV). CcBV particles are produced by specialized cells of the wasp ovaries and are injected along with the eggs into the host body. Previous studies showed that CcBV is essential for wasp's parasitism success and inhibits host cellular immune responses. However genes involved in this regulation, their targets and mode of action are largely unknown. We have characterized the different mechanisms involved in immune evasion of wasp eggs by cell imaging and found that the major phenomenon occurring after wasp oviposition was cell death of host plasmatocytes induced by apoptosis (as shown by detection of DNA fragmentation). The expression of some M. sexta genes specifically involved in apoptosis has been monitored in fat body cells and hemocytes: up-regulation was identified in both tissues. In addition three CcBV genes sharing sequence similarities to known virulence genes from other bracoviruses were shown to be expressed in these tissues making them good candidates for functional studies. Cell imaging approaches allows drawing a more accurate view on immune disruption during parasitism which together with high throughput expression analyses should allow an in depth understanding of the mechanisms involved.

Nutrition and ageing in *Drosophila melanogaster*

Matthew Piper
University College London, United Kingdom

Approximately 75 years ago it was reported that a moderate reduction in food intake without malnutrition extended the lifespan of rats. This intervention, known as calorie restriction or dietary restriction, has since been shown to be effective in enhancing lifespan in a range of organisms from yeast to primates and yet neither the dietary effectors nor the molecular mechanisms have been conclusively identified. We have been using Drosophila melanogaster to examine the mechanisms behind the dietary restriction effect. Our data clearly demonstrate that extremely small modifications to dietary amino acid balance can recapitulate the lifespan effects of wholesale food restriction. We have therefore been interested in further characterising these manipulations with the aim of uncovering their mechanism of action. I will present evidence for a rational approach to defining what constitutes a balanced diet for D. melanogaster and explain how it can clarify a great deal of work that has been undertaken to understand the mechanisms of dietary restriction.

A fructose receptor functions as a nutrient sensor in the *Drosophila* brain

Tetsuya Miyamoto[1], Jesse Slone[2], Xiangyu Song[3], Hubert Amrein[4]

[1]College of medicine, Texas A&M Health Science Center, U.S.A., [2]College of medicine, Texas A&M Health Science Center, U.S.A., [3]College of medicine, Texas A&M Health Science Center, U.S.A., [4]College of medicine, Texas A&M Health Science Center, U.S.A.

Internal nutrient sensors play important roles in feeding regulation, yet virtually nothing is known about their molecular nature. Here we show by using Ca2+ imaging and behavioral experiments that the Drosophila gustatory receptor GR43a functions as a fructose taste receptor and a internal nutrient sensor. Fructose is a low abundant hemolymph sugar whose concentration increases several fold in response to nutritious carbohydrate consumption. Feeding experiments indicate that expression of GR43a in the brain is sufficient to detect nutritious carbohydrates. Moreover, the GR43a expressing brain neurons promote feeding in hungry flies and suppress feeding in satiated flies, suggesting opposite roles in the regulation of food consumption. This notion is supported in an odor-conditioning assay, which shows that artificial activation of GR43a brain neurons is perceived as pleasant in hungry, but unpleasant in satiated flies. Thus, our studies have identified a nutrient sensor in the brain that assigns valence to feeding experiences in a satiation-dependent manner.

Central neurons modulating feeding motor rhythms in *Drosophila*

Michael Pankratz
University of Bonn, Germany

Drosophila has been a powerful genetic model for studying different types of behaviors. Numerous elegant studies have combined genetic, behavioral and optical techniques to study pheromone control of mating, chemosensory signaling and olfactory learning. For feeding behavior, which has attracted much recent interest, most of the studies have been in the context of response to external olfactory/gustatory cues, or to internal hunger states. By contrast, very little is knowns on the central processes that control the motor circuits of these behaviors. We have combined electrophysiological and genetic approaches to analyze the feeding motor circuits in the Drosophila larval central nervous system. Neuronal activity of selected neurotransmitter and neuropeptide expressing cells was manipulated by temperature-inducible and optogenetic tools. We identified central serotonergic neurons that set the motor rhythm frequency of pharnygeal pumping. Axon tracing with photoactivatable GFP and live calcium imaging revealed rhythmically active glutamatergic and serotonergic neurons that send projections to the feeding apparatus and the enteric nervous system. Glutamatergic clusters comprise the feeding motor neurons and show neuritic arborizations in the subesophageal ganglion (SOG). A novel cluster of four serotonergic cells arborize in an overlapping SOG region and direct the activity of nerves that project to the alimentary tract. These results indicate that central serotonergic system coordinates multiple neural circuits underlying food intake and digestion.

The hungry fly larvae: strain-specific phenotypic and nutrient signaling responses to varying food

Spencer T Behmer[1], Lisa Ellis[2], Aaron Tarone[3]

[1]Texas A&M University, U.S.A., [2]Texas A&M University, U.S.A., [3]Texas A&M University, U.S.A.

Food nutrient content can have profound effects on organismal traits ? human obesity is perhaps the best-known example. However, genetic differences between individuals may modulate phenotypic responses, even when individuals eat nutritionally similar foods. In this study we use Drosophila melanogaster to study how variation in food protein-carbohydrate content interacts with natural genetic variation to affect developmental processes and gene expression patterns. We conducted two sets of experiments, using fly larvae. In our first experiment we reared our three fly strains on three diets that had optimal protein-carbohydrate ratios, but three different nutrient densities (ND). Performance responses (survival, mass gain, developmental time, lipid composition) were consistent across strains, and consistently improved as nutrient density increased. We observed numerous ND-by-strain interactions with respect to nutrient signaling responses, although foxo, Ilps, and InR responses showed decreased expression as nutrient densities decreased. In our second experiment our three fly strains were reared on one of four diets with different protein-carbohydrate ratios. Survival for two of our fly strains was similar across the four diets, but survival of the third strain dropped as the protein-carbohydrate ratio of the diet increased; this strain also appeared to be obesity-resistant on carbohydrate-biased treatments. Nutrient signaling responses generally showed strong diet-by-strain interactions. However, TOR signaling consistently decreased as the protein-carbohydrate ratio increased, while slif signaling was strain specific. Collectively our results provide unique insights, both at the phenotypic and gene expression level, about how food protein-carbohydrate quantity and quality affects physiological processes, including the contribution of genetic variation.

Evolving obesity resistance and metabolic-thrift in the genetic model organism - *Drosophila melanogaster*

Lindsey Jane Gray[1], Alisha Anderson[2], David Raubenheimer[3], Stephen James Simpson[4]

[1]University of Sydney/CSIRO, Australia, [2]CSIRO, Australia, [3]Massey University, New Zealand, [4]University of Sydney, Australia

Understanding the inheritance of an obesity-prone metabolic phenotype at the molecular scale (that of genes and their regulation) could yield therapies, and inform preventative health care. Taking advantage of their short generation time, annotated genome, and the remarkable conservation of metabolic physiology among metazoans, we have used the model organism Drosophila melanogaster to begin testing how nutritional phenotypes evolve in response to changing nutritional environments. The aim has been to use laboratory selection experiments to establish the extent to which populations track shifts in their nutritional-environment, to discover the contribution of population genetic and epigenetic effects, and to use nutrigenomics to reveal molecular pathways mediating these responses.

The honeybee: A sugar junkie

Geraldine Wright[1], Pier Paoli[2], Daniel Stabler[3]

[1]Newcastle University, United Kingdom, [2]Newcastle University, United Kingdom, [3]Newcastle University, United Kingdom

Eusocial bees are important pollinators of native and agricultural plants worldwide, but we know surprisingly little about their nutritional needs. Recent applications of the Geometric Framework to study the nutrition of adult workers have shown that adult honeybees are relatively protein intolerant: they die faster on high protein diets, and the rate at which this occurs depends on the kinds of protein they are fed. Here, I will report recent work from my lab that examines the physiological basis of protein intolerance in adult worker honeybees. We convincingly show that queenless adult workers confined to artificial liquid foods composed of sucrose and the 10 essential amino acids go through two phases of adult life: for the first week, they can tolerate a much higher amount of protein, whereas after this week, their protein tolerance sharply decreases. All adult workers we examined regulated their intake of the solutions to a carbohydrate target without regard for protein ? even if they were more likely to die from eating protein. We also show that the bee's gustatory sensitivity to solutions containing amino acids corresponds to protein tolerance during both phases. I will also compare these findings to other work from my lab investigating the nutritional requirements of another eusocial bee : the adult worker bumblebee.

Nutritional limitation of food chain length

Shawn M. Wilder[1], Michael Norris[2], David Raubenheimer[3], Stephen J Simpson[4]

[1]University of Sydney, Australia, [2]University of Sydney, Australia, [3]Massey University, New Zealand, [4]University of Sydney, Australia

Recent work has shown that the nutritional composition of food items can have important consequences for the growth and reproduction of predators and that some predators will tightly regulate their diet. Predator diet regulation could have important consequences for the structure and function of food webs depending upon the nutritional composition of prey at different trophic levels. We examined the consequences of predator nutrition for food chain length in terrestrial arthropod communities. We first surveyed the nutritional composition of arthropods at different trophic levels. In general, arthropods at higher trophic levels had higher concentrations of protein and lower concentrations of lipid in their bodies than arthropods at lower trophic levels. Feeding experiments with herbivorous and predatory prey indicated that these differences in whole-body nutrients reflect differences in the nutrients that predators ingest when feeding on arthropods. Finally, we examined short-term nutrient assimilation of consumers at different trophic levels and found that herbivores primarily gained lipid, primary carnivores gained both lipid and protein and secondary carnivores primarily gained protein. Our results suggest that non-protein energy becomes increasingly limited at higher trophic levels and that, as a consequence, predators may need to feed down the food chain (e.g., on herbivores) to maintain adequate intake of non-protein energy (e.g., lipid). Hence, diet regulation of carnivores may be an important factor limiting food chain length.

Understanding social behaviour through nutrition: Collective decisions in fruit flies

Mathieu Lihoreau[1], Stephen J. Simpson[2]
[1]*The University of Sydney, Australia,* [2]*The University of Sydney, Australia*

In recent years, research on collective animal behaviour has revolutionized the study of social behaviour, identifying how simple interactions between individuals mediate complex group-level phenomena in a wide diversity of species. The improved understanding of the mechanisms underlying these social behaviours also has raised novel explanations for their evolution. Using the Geometric Framework of nutritional ecology, we will illustrate how nutrition regulates social interactions in the gregarious fruit fly Drosophila melanogaster. Free flying adults were observed foraging on chemically defined food sources varying in their protein to carbohydrate ratio. When given a choice between a nutritionally balanced food (optimal P:C ratio) and a nutritionally imbalanced food, grouped flies selected the optimal food source more accurately than isolated conspecifics, an emergent property of swarm intelligence in animal groups. When food sources were imbalanced but nutritionally complementary, grouped flies synchronised their spatio-temporal distribution, allowing them to balance their diet collectively by visiting foods sequentially. We developed an agent-based model to explore the collective behaviour of flies and their adaptive values in complex nutritional environments. Our findings highlight the regulatory role of nutrition in the emergence of social behaviour in 'simple' insect groups and pave the way for further examination of the impact of nutritional constraints on social evolution using novel and empirically testable predictions arising form nutritional ecology.

Nutritional immunology: A multi-dimensional approach

Fleur Ponton[1], Kenneth Wilson[2], Andrew J Holmes[3], Sheena C Cotter[4], David Raubenheimer[5], Stephen J Simpson[6]

[1]University of Sydney, Australia, [2]Lancaster University, United Kingdom, [3]University of Sydney, Australia, [4]Queen's University Belfast, United Kingdom, [5]Massey University, New Zealand, [6]University of Sydney, Australia

Nutrition is critical to immune defence and resistance to pathogens, with consequences that affect not only the health, welfare and reproductive success of individual organisms, but also have profound ecological and evolutionary implications. Considering the complex nature of nutritional immunology, we argue that a description of the network of interactions that define the relationships between nutrition, immune function, infection, and microbiota is essential to provide a more comprehensive and robust understanding of the key determinants of the outcome of host-pathogen interactions. Using the Geometrical Framework for nutrition, we measured these relationships using Drosophila melanogaster as a model.

Variety is the spice of life: a 21st century reappraisal of dietary mixing in a generalist insect herbivore

Heiko Vogel[1], Gregory Sword[2], Spencer T Behmer[3]
[1]Max Planck Institute for Chemical Ecology, Germany, [2]Texas A&M University, U.S.A., [3]Texas A&M University, U.S.A.

Generalist insect herbivores face complex challenges when feeding. Aside from encountering variation in nutrient content, both within and between plants, herbivorous insects regularly encounter nonnutritive plant compounds. Furthermore, different plants can contain different types and/or amounts of plant allelochemicals. The challenge, therefore, is to balance the need to eat to match nutritional requirements against limiting the intake of potentially harmful toxins. Work by Bernays and her colleagues in the early 90s demonstrated that generalist herbivores often benefited from eating a mixed diet, although mechanistic reasons for this enhanced growth could only be speculated. In this study, we reared early instar nymphs of the desert locust (Schistocerca gregaria) on two host plants (Schouwia purpurea (Brassicaceae, containing high levels of glucosinolates) and Hyoscyamus muticus (Solanaceae, containing high levels of tropane alkaloids)) occurring in its native range. Performance, measured in terms of survival and days to molting, was best for nymphs on the mixed plant treatment, relative to the single plant treatments. We then used a custom microarray approach to reveal novel insights into the benefit of diet mixing. The transcriptional responses of S. gregaria on the different treatments show markedly unique gene expression patterns. We highlight some of the key differences, and discuss the power of using molecular approaches to better understand the functional benefits of diet mixing in generalist insect herbivores.

Polygalacturonase activity in phytophagous beetles: One way to utilize plant cell wall polysaccharides

Roy Kirsch[1], Yannick Pauchet[2], Heiko Vogel[3], David G. Heckel[4]

[1]Max Planck Institute for Chemical Ecology, Germany, [2]Max Planck Institute for Chemical Ecology, Germany, [3]Max Planck Institute for Chemical Ecology, Germany, [4]Max Planck Institute for Chemical Ecology, Germany

Primary plant cell walls are composed of approximately 90 % polysaccharides such as cellulose, hemicellulose and pectins. To utilize this massive carbon source the fibrous wall has to be deconstructed. Cellulolysis in the guts of termites is the text book example for carbohydrolytic activities in herbivorous insects. It has been shown that not only their gut microbes but termites themselves contribute to cellulose digestion by expressing cellulases. In addition, due to massive genome and transcriptome sequencing, the amount of insect putative plant cell wall degrading enzymes (PCWDEs) in general increases rapidly. Nevertheless, most characterized PCWDEs are of microbial origin and little is known about carbohydrolysis and the underlying enzymatic machinery encoded by herbivorous insect genomes. Here we report the ability of the leaf beetle Phaedon cochleariae to degrade the pectin polygalacturonan. Initial assays with their gut fluid demonstrated the presence of polygalacturonase (PG) activity. By transcriptome analysis nine putative PG encoding sequence tags could be identified. After cloning and heterologous expression followed by zymogram and agarose-diffusion assays, three of them turned out to be active PGs. Analysis of the gut fluid proteome verified the three active PGs and one inactive being present in the gut of Phaedon. To get insights in the role of PGs with respect to nutrition and herbivore host-plant interaction in general, we investigated their expression pattern and tested the direct interaction between PGs and host plant produced PG inhibitory proteins, as it is known that those act as plant defense against phytopathogenic microbes.

Isothiocyanate metabolism in lepidopteran herbivores

Katharina Schramm[1], Daniel Giddings Vassao[2], Michael Reichelt[3], Jonathan Gershenzon[4]

[1]Max Planck Institute for Chemical Ecology, Germany, [2]Max Planck Institute for Chemical Ecology, Germany, [3]Max Planck Institute for Chemical Ecology, Germany, [4]Max Planck Institute for Chemical Ecology, Germany

Isothiocyanates are the principal defensive compounds of plants in the order Brassicales, being formed from glucosinolates when plant tissue is damaged, for instance by chewing herbivores. Isothiocyanates have consistently been shown to exert negative impacts on insect herbivores in terms of growth rate, developmental time and survival. However, several lepidopterans are specialised to feed on Brassicales. The key mode of adaptation in these insects is thought to be the avoidance of isothiocyanate formation by different biochemical strategies. A number of generalist lepidopterans occasionally also feed on Brassicales, yet it is not clear how they cope with isothiocyanates. Against this background, we investigated how larvae of the generalist lepidopteran Spodoptera littoralis metabolise isothiocyanates using [14C]-labelled 4-methylsulfinylbutyl glucosinolate as a tracer. The major metabolic products of the corresponding isothiocyanate were glutathione conjugate derivatives. Thus, S. littoralis did not avoid isothiocyanate formation, but instead metabolised and excreted these compounds. Additional studies revealed that this noctuid could transform a variety of different isothiocyanates to their corresponding glutathione conjugates. We are currently investigating the role of glutathione-S-transferases in forming these metabolites. Unexpectedly, a large proportion of the labelled isothiocyanate were excreted unaltered, raising further questions regarding the mechanism of toxicity of isothiocyanates and their possible in vivo targets. We are hence exploring the biochemical basis of isothiocyanate toxicity in S. littoralis. Results from medical studies suggest that oxidative stress, mediated for example through glutathione depletion, may play a role in the observed toxicity, a possibility we are currently exploring in different generalist insect herbivores.

Leaf-miner insects modulate nutritional intake through an unexpected association with endosymbiotic bacteria

David Giron[1], Melanie Body[2], Jerome Casas[3], Jean-Paul Monge[4], Arnaud Lanoue[5]

[1]CNRS - University F. Rabelais, France, [2]CNRS - University F. Rabelais, France, [3]CNRS - University F. Rabelais, France, [4]CNRS - University F. Rabelais, France, [5]University F. Rabelais, France

Nutritional requirements of animals are multidimensional and change qualitatively and quantitatively over time. In parallel, the nutritional environment is frequently highly variable both in space and time and food sources are composed of a wide array of nutrient molecules in various ratios and concentrations combined with non-nutritive molecules. Finally, plants are known to rapidly respond to herbivore attacks by reconfiguring their metabolism in order to reduce herbivore food acquisition. As a consequence, individuals need to adopt specific pre- and post-ingestive regulatory systems to match their energetic requirements. In the context of nutritional ecology of insects, endophagous organisms are peculiar for several reasons: first, most leaf-miner and gall-inducer arthropods display high levels of fidelity to particular host-plant species. Second, their concealed habit in a confined environment prevents most endophagous larvae from switching between various plants or plant species during their development. As a consequence, while endophagous insects by their feeding habit secure their nutrition and shelter, they also have to adopt specific feeding strategies allowing them to meet their energetic requirements, to face variations in food composition and nutritional needs, and to counteract plant defensive mechanisms. Our results on the Malus domestica/Phyllonorycter blancardella plant-leaf mining system show the ability of this leaf-miner caterpillar to manipulate its host plant in order to generate a microenvironment with all the nutrient supply needed for its survival and a decrease in plant defense compounds within the mined area. Insect endosymbiotic bacteria play a primary role in this manipulation of the host plant physiology.

Putting a complete nutrient budget to the acid test - and using it

Jerome Casas[1], Melanie Body[2]
[1]University of Tours, France, [2]University of Tours, France

We completed and tested a complete dynamic nutrient budget over the lifetime of an animal, the parasitic wasp Eupelmus vuilletti (Hymenoptera), in absence and in continuous presence of hosts using colorimetric essays and respirometry (CO2 & 02). This insect uses hosts, a bruchid beetle, for both oviposition and food. The nutrients are classified as proteins, carbohydrates and lipids. The model encompasses a rather large number of experimentally estimated parameters. We obtained good quantitative predictions in the absence of hosts and good qualitative predictions with continuous access to hosts. The time varying host-feeding & oviposition occurrences as well as fluctuating respiration and reserve uses all lead to highly dynamical and counterintuitive trends sustaining the animal' homeostasis. Given it good behaviour and predicting abilities over many data sets collected within a decade long period, we are now possessing a firmly based, robust model. The model was then used to explore nutrient and energy dynamics in a fluctuating environment. We varied experimentally the access to hosts for oviposition and feeding over the animal lifetime, and quantified the protein contents of females. The model was able to rank correctly the proteins content of females in different treatments of host availability. The particularly vexing problem of the overriding impact of teneral conditions as well as possible extensions of the model will be presented.

Plant quality is more than just nutrients: Insect herbivores can choose microclimates to achieve nutritional homeostasis

Fiona Clissold[1], Stephen Simpson[2]
[1]*The University of Sydney, Australia,* [2]*The University of Sydney, Australia*

Temperature and nutrition interact to affect the life histories of ectotherms. These interactions are generally believed to be mediated via metabolic rate, rather than by changes in the rates and ratios at which particular nutrients are digested, absorbed and utilized. We show that the rates and balance of protein and carbohydrate absorbed from particular host plants by a model herbivore, the locust, is temperature dependent. Furthermore, locusts were able to choose body temperatures so that protein and carbohydrate were differentially absorbed to redress experimentally imposed nutrient imbalances. Hence, 'diet quality' is temperature sensitive and insect herbivores can manipulate this relationship to their own ends. These findings suggest micro-climatic effects may be of more importance than previously appreciated for understanding the consequences changed environmental temperatures and microclimate on animal-plant interactions.

Interplay of nutrition and temperature affecting food intake and performance in insects: A case study from caterpillars

Kwang Pum Lee
Seoul National University, Republic of Korea

Temperature and nutrition are the two most prominent environmental determinants of fitness in insects. However, it remains largely unexplored how variations in food nutrient quality mediate the relationships between ambient temperature and various aspects of insect performance with respect to behavior, physiology and life-history. The present study investigates the separate and combined effects of ambient temperature and nutrient imbalance on key components of fitness, food intake and selection, and post-ingestive nutritional physiology in two species of caterpillars, Spodoptera exigua and S. litura (Lepidoptera: Noctuidae). In the no-choice test, caterpillars were confined to one of six nutritionally imbalanced diets that varied in protein and carbohydrate content (P:C = 42:0, 35:7, 28:14, 21:21, 14:28, 7:35) under five different temperatures ranging from 12 to 42 °C. Caterpillars grew and ate faster when temperature rose gradually up to 34°C but suffered high mortality and reduced efficiencies of nutrient utilization. Response surfaces that relate temperature, nutrition, and larval performance showed that optimal temperature for growth and survival differed considerably and that the thermal sensitivities of key life-history traits were constrained by dietary imbalance, suggesting significant temperature-by-nutrient interactions. When allowed to select their preferred diet, caterpillars in the warmer thermal regime (above 30°C) preferentially selected carbohydrate-rich diet whereas those in the cooler (below 30°C) consumed the equal ratio of protein to carbohydrate. Such temperature-induced shift in diet preferences allows caterpillars to supplement extra energy that is required for fueling elevated metabolic rates when living and growing in the warmer thermal environment.

Low plant nitrogen content and high population density enhance migratory characters in a polyphenic locust

Arianne Cease[1], Jon Harrison[2], Shuguang Hao[3], Le Kang[4], Danielle Niren[5], James Elser[6]

[1]Arizona State University, U.S.A., [2]Arizona State University, U.S.A., [3]Chinese Academy of Sciences, China, [4]Chinese Academy of Sciences, China, [5]Arizona State University, U.S.A., [6]Arizona State University, U.S.A.

Locusts present an impressive and well-studied example of phenotypic plasticity in which population density regulates a variety of behavioral, morphological, and physiological traits that often culminate in migratory swarms. Oedaleus asiaticus, a north Asian locust, has outbreaks and migratory swarms comprised predominantly of brown morphs. Heavy livestock grazing promotes outbreaks by lowering plant nitrogen content and likely lowering the protein:carbohydrate ratio to the optimal range for this locust. However, it is unclear if a change in plant quality can modulate the effect of density on phase characteristics. We found that locusts reared at high population density and fed low-N plants (i.e. plants that are high quality for O. asiaticus) had the most enhanced migratory characteristics while locusts fed high-N plants (i.e. deleterious for this locust) consistently had decreased expression of migratory characters. These results do not support existing paradigms that poor-quality resources increase the expression of migratory phenotypes. We then compared feeding habits of the brown (outbreak) and green (non-outbreak) morphs. There was no difference in plant preference nor protein:carbohydrate intake target ratio; however, when confined to diets extreme in their protein:carbohydrate ratios, green locusts decreased consumption and brown locusts maintained a similar consumption rate on all diets. From these results we infer that the green morph strategy may be most beneficial for sedentary insects confined to limited food choices to avoid long-term deleterious effects of consuming an unbalanced diet, while the brown morph strategy of being more willing to consume suboptimal foods may be most beneficial for roaming insects.

Nutrient regulation strategies in wing polymorphic crickets reflect life history allocation trade-offs

Rebecca Maria Clark[1], Anthony J Zera[2], Spencer T Behmer[3]

[1]Texas A&M University, U.S.A., [2]University of Nebraska, Lincoln, U.S.A., [3]Texas A&M University, U.S.A.

An organism's life history and phenotype should be intimately linked to optimal nutrient regulation strategies, yet actual demonstrations of such connections are rare. Here, we show how a well-studied trade-off between dispersal and reproduction in the wing-polymorphic cricket Gryllus firmus is tied to differences in feeding behavior. In a "choice" experiment, we offered female crickets selected either for dispersal (long-winged individuals, LW) or reproduction (short-winged individuals, SW) access to two imbalanced, but complementary foods that varied in their protein and digestible carbohydrate content. In a second, "no-choice" experiment, we confined crickets to one of five imbalanced foods that were either protein- or carbohydrate-biased. In both cases, we measured crickets' food intake, mass gains, and lipid profiles. LW crickets allowed to self-select between foods chose a diet that was more carbohydrate-biased than that selected by SW crickets, resulting in higher lipid gains but equal mass gains. When confined to single foods, with a range of protein-carbohydrate ratios, SW crickets over-ate whichever nutrient was available in excess; these crickets gained more mass, yet had similar lipid profiles compared to the LW crickets. These patterns show that in this species feeding behavior directly influences the dispersal/reproduction trade-off, elucidating how behavioral and physiological processes drive the expression of this phenotype.

Introduction

Jose Ribeiro
National Institutes of Health, U.S.A.

Insect saliva helps the feeding and digestion of food in various ways. Physically, saliva helps to dissolve solid food, as in the house fly, or to seal the mouthparts of feeding aphids when tapping their plant hosts vessels. Biochemically, saliva has enzymes that assist the digestion of the ingested food, or the prey itself in the case of saliva injected by predators. Pharmacologically, the saliva of insects feeding on living organisms can modify their physiology to increase the success of the meal, by injection of paralytic substances by predators or by injection of anti-clotting agents by blood feeding arthropods. Saliva of vector arthropods is also the vehicle for pathogen delivery and/or modifies the site of pathogen injection and accordingly becomes a target for vaccine interventions. Saliva of blood sucking insects consistently have anti-clotting, anti-platelet, vasodilatory and immunomodullatory components. Recent transcriptome analysis indicate that the salivary potion of these organisms contain 50-125 polypeptides in insects and several hundreds in ticks. Possibly due to the host immunological response, these proteins are at a very fast pace of evolution and many salivary proteins have new folds and unknown function. Recent advances in our laboratory related to the discovery of the function of these novel proteins will be presented.

Vector saliva as a vaccine target to prevent infectious diseases

Jesus G. Valenzuela
National Institute of Allergy and Infectious Disease, U.S.A.

In vector-borne diseases the contribution of vector saliva in parasite establishment in mammalian hosts is largely ignored. We tested the hypothesis that vector salivary proteins can modulate the host immune response to the parasite and protect the host against infection. Injection of a recombinant sand fly salivary protein without adjuvant induced a long-lasting cellular immunity in mice and conferred powerful protection against the Leishmania parasite delivered by sand fly bites. This protection is antibody independent and is abrogated by depletion of CD4+ T cells. This is the first evidence that a vector protein can confer protection against sand fly transmitted parasites. We propose that this salivary protein is an immunomodulator that can drive an early and controlled response to a sand fly-transmitted virulent Leishmania somewhat mimicking "leishmanization"- induced protection but without its associated pathology.

Mosquito salivary glands as vaccine delivery targets

Shigeto Yoshida[1], Daisuke Yamamoto[2], Hiroyuki Matsuoka[3]
[1]Kanazawa University School of Pharmacy, Japan, [2]Jichi Medical University, Japan, [3]Jichi Medical University, Japan

We have established a robust salivary gland-specific transgene expression in transgenic (TG) Anopheles stephensi mosquitoes. Under control of a newly isolated salivary gland-specific promoter, robust expression of DsRed tetramer (tDsRed) protein was achieved in the cytoplasm (cytoplasmic form) of the salivary gland cells of distal-lateral lobes, where the sporozoites invade preferentially. This salivary gland-specific promoter drives the expression of Anopheline Anti-Platelet Protein (AAPP), which exhibits a strong and specific inhibitory activity toward collagen-induced platelet aggregation. Using the AAPP promoter, we have recently generated a TG mosquito which secrets a foreign protein as a component of saliva during blood feeding. The foreign protein is SP15 fused to DsRed monomer protein (mDsRed-SP15). The SP15 antigen has originally been identified from sand fly saliva as a leishmania vaccine candidate antigen. We observed that the mDsRed-SP15 protein was accumulated in the cavity and duct of the salivary gland. Interestingly, mice repeatedly bitten by the TG mosquitoes had anti-SP15 antibodies, indicating injection of the mDsRed-SP15 protein during blood feeding. These results may suggest a possibility that a TG mosquito expressing a vaccine antigen in the saliva can delivery its vaccine to the hosts (known as "Flying vaccinator"). However, we are aware that the concept of the flying vaccinator is not in itself going to be a practicable method of disease control. So, the present study is a model case and we intend to apply this system for elucidation of saliva-malaria sporozoite interaction.

Vector salivary antigens as epidemiological markers

Anne Poinsignon[1], Pape Drame[2], Alexandra Marie[3], Herbert Noukpo[4], Sylvie Cornelie[5], Souleymane Doucoure[6], Marie Rossignol[7], Francois Mouchet[8], Franck Remoue[9]

[1]IRD - Insitut de Recherche pour le Developpement, France, [2]IRD - Insitut de Recherche pour le Developpement, France, [3]IRD - Insitut de Recherche pour le Developpement, France, [4]IRD - Insitut de Recherche pour le Developpement, Benin, [5]IRD - Insitut de Recherche pour le Developpement, Benin, [6]IRD - Insitut de Recherche pour le Developpement, France, [7]IRD - Insitut de Recherche pour le Developpement, France, [8]IRD - Insitut de Recherche pour le Developpement, France, [9]IRD - Insitut de Recherche pour le Developpement, Benin

The study of human-vector immune relationships could allow several applications for the control of vector-borne diseases. Indeed, some salivary proteins from blood-feeding arthropods could induced a specific immune responses in human populations exposed to arthropod vectors bites. So, why do not use the immunogenic properties to develop of biomarker of human bites exposure? The case of Anopheles-Plasmodium complex and similar approach for Aedes-borne diseases (arbovirus) will be focused here. One hypothesis is that human immune response and especially antibody (Ab) response to whole saliva of mosquito could be an epidemiological biomarker of human exposure to vector bites. In the objective to increase the specificity to vector exposure, the second step was to identify salivary proteins i) specific to Anopheles/Aedes genus and ii) antigenic in individuals exposed to malaria or arbovirus diseases. First, the identification of antigenic salivary proteins of mosquito by an immuno-proteomic approach was assessed. The second step was to design peptide sequences, from one selected mosquito salivary protein using a bioinformatic approach, taking into consideration i) their potential antigenic properties and ii) the absence of cross-reactivity with other arthropods/organisms. For malaria, the specific IgG Ab levels were then evaluated in African children in different context of malaria. From five peptides, only one peptide (gSG6-P1) presented all criteria to be an optimal candidate biomarker for evaluating human exposure to An. gambiae and An. funestus bites and interestingly for evaluating the efficacy of vector control. The same strategies developed for measuring human exposure to Aedes will be also presented.

We demonstrated that tick cysteine protease inhibitors (cystatins) are essential for feeding success of Ixodes scapularis, the vector of Lyme disease agents in the eastern and central USA. One of these inhibitors, named sialostatin L2, facilitates both Borrelia burgdorferi and Anaplasma phagocytophilum establishment in the vertebrate host, uncovering that upon host colonization two different tick-borne pathogens exploit an essential protein for tick feeding success. The pharmacological action of an I. scapularis cysteine protease inhibitor, named sialostatin L, has the potential to alleviate the symptoms of autoimmune encephalitis and allergic asthma in mice. Tick saliva also contains serine protease inhibitors which target various vertebrate host proteases; we already described the structural basis for the unique target specificity and pharmacological properties of a serine protease inhibitor of the serpin superfamily, named IRS-2. We propose that the role of proteolysis regulation by tick salivary secretion is prominent in the tripartite interaction between ticks, the vertebrate hosts and tick borne pathogens. Hematophagy has resulted in the adaptation of the ticks to the vertebrate hosts through the inclusion in their salivary secretion of substances with potent pharmacological action. We currently test whether ticks can serve as model organisms for the discovery in their salivary glands of bioactive molecules with unique molecular targets and mechanism of action in the host. Beyond investigating the structural basis for their action we also test the potential of these molecules for future drug development in animal models of various diseases.

Insect saliva in plant insect interactions

David Prince[1], Marco Pitino[2], Alexander Coleman[3], Claire Drurey[4], Saskia A Hogenhout[5]

[1]The John Innes Centre, United Kingdom, [2]The John Innes Centre, United Kingdom, [3]The John Innes Centre, United Kingdom, [4]The John Innes Centre, United Kingdom, [5]The John Innes Centre, United Kingdom

Piercing-sucking hemipteran insects, such as aphids, display typical feeding behaviours suggesting active suppression of plant defence responses (1). Functional genomics of the green peach aphid Myzus persicae resulted in the identification of effectors that are present in the aphid saliva and modulate plant processes (2). Silencing of these effector genes by plant-mediated RNA interference (RNAi) in M. persicae (3) reduces this aphid's fertility on plants, while M. persicae has enhanced fertility on transgenic Arabidopsis plants that express the M. persicae effector genes. Interestingly, M. persicae fertility did not increase on plants that express effectors of a closely related aphid species, the pea aphid Acyrthosiphon pisum, that are highly similar in amino acid sequence to the M. persicae effectors. A. pisum is a legume specialist, and does not use Arabidopsis as a host. Thus, aphid effectors have adapted to modulate plant processes to the benefit of aphids in specific plant hosts. We also have evidence that M. persicae suppresses the plant basal immunity, i.e. Pathogen-Associated Molecular Pattern (PAMP) Triggered Immunity (PTI). We have identified plant receptors involved in the induction of PTI to aphids and characterized an aphid effector that suppresses PTI. This is the first evidence that an immune receptor is involved in host perception of an insect pest. Altogether, our work provides new avenues for research to improve insect pest control. Proteomics of aphid salivary proteins

Frederic Francis[1], Sophie Vandermoten[2], Edwin DePauw[3], Eric Haubruge[4]

[1]University of Liege - Gembloux Agro-Bio Tech, Belgium, [2]University of Liege - Gembloux Agro-Bio Tech, Belgium, [3]University of Liege, Belgium, [4]University of Liege - Gembloux Agro-Bio Tech, Belgium

Relations between insects and plants are complex. By both direct and indirect mechanisms, locally or systemically, plants defend themselves toward a diversity of insect pests. To induce these defense pathways, elicitation signals have to be perceived by plants, including both mechanical and biochemical factors according to the pest feeding behaviour. Until now, chewing feeders inducing large plant damages were the most studied models for plant defense elicitation phenomena. Several elicitors were already identified : the volicitin in Spodoptera exigua, a glucose oxidase in Helicoverpa zea and a β-glucosidase in Pieris brassicae. A specific signature hypothesis was oftenly cited to explain the diversity of elicitation compounds in this range of insect saliva. Other herbivores, such as aphids are also largely distributed on a diversity of host plant with significant specificities. We performed proteomic tasks to characterize potential elictors in several aphid species but also in different aphid clones from the same species according to different pattern of endosymbionts. Complementary approaches were performed to identify and characterize aphid salivary proteins : separation by one and two dimension electrophoresis coupled with Maldi-Tof identification, use of nano-liquid chromatography coupled with mass spectrometry (ESI MS-MS), functional tests on whole plants or cell culture using aphid saliva (assessing the oxydative burst, pH changes, plant volatile patterns and proteomic changes in plant materials). One of the interesting protein found in aphid saliva was a glucose oxydase. This finding was discussed in relation to the specific signature hypothesis in plant-insect relations and potential perspective in aphid pest control.

Function and antigenicity of mosquito salivary proteins

Bruno Arca[1], Fabrizio Lombardo[2], Raffaele Ronca[3], Cinzia Rizzo[4], Gabriella Fiorentino[5], David Modiano[6]

[1]Sapienza University of Rome, Italy, [2]Sapienza University of Rome, Italy, [3]University Federico II, Naples, Italy, [4]Sapienza University of Rome, Italy, [5]University Federico II, Naples, Italy, [6]Sapienza University of Rome, Italy

Substantially improved knowledge of mosquito salivary repertoires has been achieved in the last decade through transcriptome and expression/functional studies. Nevertheless, a large number of salivary proteins are so far without a function and our understanding of the effects of mosquito saliva on host immune response and pathogen transmission/infection is still rudimentary. We recently characterized two Anopheles gambiae salivary proteins restricted to anopheline mosquitoes and involved in hematophagy: gSG6 and cE5. The first helps mosquito blood feeding by a still unknown mechanism, the second is a highly specific fast- and tight-binding thrombin inhibitor. Both proteins are immunogenic to humans and evoke different humoral responses in exposed individuals from a malaria hyperendemic area. The IgG response to gSG6 decreased with age whereas anti-cE5 IgG levels showed an opposite trend. IgG4 was the dominant anti-gSG6 IgG subclass (IgG4>IgG1), instead IgG1 was the main anti-cE5 antibody (IgG1>>IgG4). Since IgG1 and IgG4 are often considered as markers of Th1- and Th2-type responses we believe we have identified two salivary antigens with strikingly different antigenic properties: (i) gSG6, triggering a Th2-type response, with high IgG4 levels and induction of tolerance; (ii) cE5, eliciting a Th1-type response, with high IgG1 levels and no development of tolerance. The availability of salivary components triggering differential host responses is expected to help dissecting the complexity of the human immune response to mosquito saliva and to provide a deeper understanding of the potential for mosquito salivary proteins to be exploited in the fight against vector-borne diseases.

Role of saliva in vectors of dengue virus transmission

Dorothee Misse[1], Pornapat Surasombatpattana[2], Rodolphe Hamel[3], Sirilaksana Patramool[4], Natthanej Luplertlop[5], Hans Yssel[6]

[1]UMR IRD 224/CNRS 5290/UM1/UM2, France, [2]UMR IRD 224/CNRS 5290/UM1/UM2, France, [3]UMR IRD 224/CNRS 5290/UM1/UM2, France, [4]UMR IRD 224/CNRS 5290/UM1/UM2, France, [5]Mahidol University, Bangkok, Thailand, [6]INSERM Montpellier, France

Dengue virus (DENV) infection is the most prevalent mosquito-borne viral diseases in the world. Vector-mediated transmission of DENV is initiated when a blood-feeding female Aedes mosquito injects saliva, together with the virus, into the skin of its mammalian host. Understanding the role of skin immune cells in the activation of innate immunity to DENV at the early times of infection is a critical issue that remains to be investigated. The purpose of our study was to assess the contribution of human keratinocytes as potential host cells to DENV. We show that primary human keratinocytes support DENV replication with the production of negative-stranded viral RNAs inside the infected cells. In the course of DENV life cycle, we observed the activation of host genes involved in the antiviral immune responses such as intracellular RNA virus sensors. DENV infection of primary keratinocytes also resulted in up-regulation of the expression of the antiviral Ribonuclease L gene, which subsequently led to enhanced production of IFNs. We have also investigated the effect of Aedes salivary gland extract (SGE) on DENV infection in human keratinocytes. We show that Aedes SGE enhances DENV infection of human keratinocytes via the inhibition of the secretion of antimicrobial peptides and interferons by the infected cells. The results underscore the importance of Aedes saliva in the earliest events of DENV transmission.

Insect Immunology, Physiology and Neurobiology

PTTH coordinates physiological and behavioral transitions during *Drosophila* development

Naoki Yamanaka[1], Kim F Rewitz[2], Michael B O'Connor[3]

[1]University of Minnesota, U.S.A., [2]Roskilde University, Denmark, [3]University of Minnesota, U.S.A.

Prothoracicotropic hormone (PTTH) is a brain neuropeptide that regulates the timing of molting and metamorphosis in insects. PTTH activates its receptor Torso expressed in the prothoracic gland (PG), which transduces a downstream signal through the MAPK pathway to stimulate the production of the steroid hormone ecdysone. Ecdysone in turn regulates the expression of multiple genes in most larval tissues to coordinate all the physiological and morphological changes that accompany molting and metamorphosis. To date, all known functions of PTTH during insect development appear to be mediated indirectly through control of ecdysone production and release. By using Drosophila genetic tools to manipulate the function of Torso in different cell types, we have recently uncovered a novel function of PTTH that is independent of its prothoracicotropic effect on the PG. We find that PTTH acts directly on a subset of neuronal cells to regulate certain behavioral transitions that Drosophila larvae undergo prior to metamorphosis. Therefore, PTTH appears to be a master regulator of insect development via at least two parallel pathways that coordinates not only physiological and morphological changes during metamorphosis, but also at least one behavioral transition that presumably contributes to the success of this process. The significance of these independent functions of PTTH will be discussed.

The silkmoth Bombyx mori is a suitablemodel species for analysis of complex physiological and biochemical processescontrolled by neuropeptides and their receptors. To understand neuroendocrine interactions between these important regulatory molecules we determined the temporal and spatial expression patterns of all known neuropeptides and selected receptors in the CNS and peripheral endocrine organs.In situ hybridization with DNA probes combined with double/triple immunohistochemical staining revealed the presence of multiple receptors in peptidergic and aminergic central neurons as well as endocrine cells. To further examine the role of these neurons and endocrine cells, we used the baculovirus expression system for identification of neuropeptide promoters suitable for targetedexpression of selected receptors in the CNS and endocrine organs. Characterized promoters with receptors or molecular markershave been subcloned into piggyBac vectors and used for production of transgenic animals. Targeted expression of various receptors and markers revealed specific functions and unexpected neuroendocrine pathways between specific central neurons and endocrine organs. Some specific pathwaysand receptor functions will be discussed in more detail.

Drosophila short neuropeptide F (sNPF) signaling regulates lifespan, body growth, and carbohydrate metabolism through the insulin signaling

Kweon Yu
Korea Research Institute of Bioscience and Biotechnology, Republic of Korea

Drosophilashort neuropeptide F (sNPF) is processed and expressed in the nervous systems of various developmental stages. Inhibition of sNPF in the nervous system shows increased lifespan, small body size, and increased blood carbohydrate level compared to the Wild-type control flies. These are typical phenotypes of mutants in the insulin signaling, which suggest that sNPF may regulate insulin signaling. Therefore, we investigated whether sNPF regulates insulin signaling in the insulin producing cells (IPCs) and insulin target tissues. After immunostaining with the anti-serum against sNPF receptor (sNPFR1) in the fly brain, we found that sNPFR1 is localized in the plasma membrane of IPCs. When sNPF was inhibited in the neurons, the expression level of the Drosophila insulin-like peptides (Dilps) gene was decreased compared to that of the Wild-type control. Likewise, sNPFR1 suppression in IPCs reduced Dilps expression. These regulations of Dilp expression by sNPF and sNPFR1 in IPCs are mediated by ERK. In the fat body, which is the homologous tissue of mammalian liver and adipocytes, sNPF mutants inhibited the activation of Akt, induced the nuclear localization of FOXO, and increased the expression of the translational inhibitor 4E-BP. It indicates that sNPF mutants inhibited the insulin receptor signaling in the fat body. These IPCs and fat body data demonstrate that sNPF and sNPFR1 regulate lifespan, body size, and glucose metabolism through the insulin signaling.

Neuropeptides in the midgut

Jan Adrianus Veenstra
The University of Bordeaux, France

Endocine cells in the midgut of both larval and adults of Drosophila melanogaster were identified with antisera to various neuropeptides. Allatostatins A, B and C, neuropeptide F, diuretic hormone 31, tachykinins and short neuropeptide-F (sNPF) producing endocrine cells were found. Axons immunoreactive toward antisera to short neuropeptide F and pigment-dispersing factor are also present in the midgut. The Drosophila insulin 3 gene is also expressed in the midgut, but dilp3-gal4 flies suggest that it is produced muscles, not endocrine cells.

Updates of neuropeptide mediated regulation of ecdysone biosynthesis in the prothoracic glands of *Bombyx mori*

Masatoshi Iga[1], Hiroshi Kataoka[2]
[1]*University of Tokyo, Japan,* [2]*University of Tokyo, Japan*

The insect steroid hormone, ecdysone is important for the regulation of molting and metamorphosis. The ecdysone is predominantly synthesized in the prothoracic glands (PGs) from dietary cholesterol or phytosterols. The ecdysone biosynthesis is intricately regulated by neuropeptides. To date, four prothoracicotropic peptides (PTTH, FXPRL-amides, insulin and orcokinins) and three prothoracicostatic peptides (PTSP, Bommo-myosuppressin and Bommo-FMRFamides) have been identified in Bombyx mori. However, the whole regulatory mechanisms of ecdysone biosynthesis are not fully understood, and involvement of more neuropeptides is expected. To elucidate the entire pathway of ecdysone biosynthesis including its regulatory mechanisms, we performed a transcriptome analysis of the PGs in B. mori using next-generation sequencing, and found a G-protein coupled receptor (GPCR) mediated novel regulatory mechanism in the ecdysone biosynthesis. Quantitative analyses of the sterols in the cultured medium and PGs by liquid chromatography-tandem mass spectrometry revealed that a ligand of the GPCR markedly induced the ecdysone biosynthesis, and reduction of 7-dehydrocholesterol content in the PGs was observed. On the other hand, the ligand was not affected for the cholesterol content. In addition, we discuss the similarity and difference between this novel regulatory mechanism and PTTH mediated regulatory mechanism in the ecdysone biosynthesis. [This study was supported by the grant from Programme for Promotion of Basic and Applied Researches for Innovations in Bio-oriented Industry.]

Multiple transmitter systems regulate Adipokinetic Hormone Signaling in *Drosophila*

Erik C Johnson[1], Jason T Braco[2], Emily Gillespie[3], Gregory E Alberto[4], Rebecca J Perry[5]

[1]Wake Forest University, U.S.A., [2]Wake Forest University, U.S.A., [3]Wake Forest University, U.S.A., [4]Wake Forest University, U.S.A., [5]Wake Forest University, U.S.A.

Adipokinetic Hormone (AKH) is the insect equivalent of mammalian glucagon as it is the primary hormone responsible for the release of stored energy. We recently identified that the AMP-activated kinase (AMPK) as a critical factor that regulates AKH secretion via modulation of AKH cell excitability. Notably, the loss of AMPK function in AKH cells leads to a partial phenocopy of AKH cell ablations, suggesting additional regulators of AKH signaling. To identify these, we performed a genome-wide screen of peptide and amine GPCRs that potentially regulate AKH signaling. Specifically, we employed an RNAi strategy to specifically target the entire complement of peptide and amine GPCRs in Drosophila. Our prediction was that the loss of receptors that function to facilitate the release of AKH would lead to behavioral phenotypes consistent with the loss or reduced AKH function (e.g., starvation resistant, no hyperactivity). In contrast, we reasoned that the loss of receptors which normally inhibit AKH release would yield opposite phenotypes (starvation sensitivity, greater amounts of hyperactivity, etc). We identified that animals expressing RNAi targeting the receptor for the Allatostatin C (AstC-R1) show increased starvation resistance. We confirmed that AKH cells express this receptor using RNAseq and single-cell RT-PCR. Furthermore, using GCaMP as a reporter for AKH cell activation, we observe that application of AstC increases AKH secretion in an energy independent fashion. We also note an epistatic interaction of AstC and AMPK, suggesting that AstC acts to modulate AMPK activity. In addition to AstC, we will present findings on other transmitter systems.

G-protein coupled receptors for regulating ecdysteroid biosynthesis in the fruit fly *Drosophila melanogaster*

Yuko Shimada-Niwa[1], Jevgenija Maramzina[2], Ryusuke Niwa[3]
[1]*University of Tsukuba, Japan,* [2]*University of Tsukuba, Japan,* [3]*University of Tsukuba, Japan*

In this presentation we report that multiple G-protein coupled receptors (GPCRs) are involved in biosynthesis of ecdysteroids, the principal steroid hormones guiding insect molting and metamorphosis. During insect development, ecdysteroids are synthesized from dietary cholesterol in a special endocrine organ called the prothoracic gland (PG). Ecdysteroid biosynthesis in the PG is controlled in response to several external conditions, such as nutrition, temperature and photoperiod. This adaptive change of ecdysteroid biosynthesis results in flexible alterations of developmental timing and growth, which enable insects to survive in various harsh environments. However, it remains unclear how external information is transmitted to the PG to adaptively control the catalytic activities of the ecdysteroidogenic enzymes. To uncover essential genes involved in the precise regulation of ecdysteroid biosynthesis in the PG, we conducted a transgenic RNAi screen using the PG-specific GAL4 drivers and UAS-RNAi strains in the fruit fly Drosophila melanogaster. We found that developmental arrests were caused by PG-specific RNAi for genes encoding several GPCRs including neurotransmitter receptors. These phenotypes were rescued when the RNAi animals were fed 20-hydroxyecdysone-supplemented food. Moreover, the 20E titer and the expression levels of ecdysteroid biosynthetic enzyme genes significantly decreased in the RNAi animals. Interestingly, a subset of neurotransmitter-producing neurons directly innervated to the PG. Considering that neurotransmitters modulate target activities in response to external stimuli, we currently hypothesize that the neurotransmitters and their GPCRs play important roles in reflecting environmental conditions on ecdysteroid biosynthesis in the PG.

Identification of the molecular domain that confer ligand selectivity of the sex peptide receptor

Young-Joon Kim
Gwangju Institute of Science and Technology, Republic of Korea

The sex peptide receptor (SPR) mediates actions of the sex peptide (SP), a male seminal fluid protein that triggers the post-mating response in females. SPR is found in almost all sequenced insect genomes and Aplysia, whereas its ligand SP is found only in handful numbers of Drosophila species, inferring its recent evolutional origin. Previously we identified myoinhibitory peptide (MIPs) as an ancestral family of SPR ligands that is highly conserved across insect species and has the same phylogenetic distribution as SPR. MIPs are potent agonists for Drosophila, Aedes, Anopheles, Bombyx and Aplysia SPRs in vitro. In contrast to MIPs, SP is potent only on Drosophila SPR (dSPR), but not on other non-Drosophilidae SPRs. To understand how dSPR evolves its dual-ligand selectivity, we setout to identify the molecular domain of dSPR responsible for SP-sensitivity, and ask it is also required for MIP-sensitivity. We divide SPR into 8 domains, and perform a systematic domain swapping between SP-sensitive dSPR and SP-insensitive Aedes SPR (aSPR). By replacing domains of dSPR with corresponding aSPR domain systematically, we identify domain number 5 (D5) of dSPR, necessary for the SP-sensitivity. In parallel we swap aSPR domains with dSPR ones and find D5 domain also confers SP-sensitivity on aSPR. Together both analyses equivocally show D5 domain is necessary and sufficient for the SP-sensitivity. Currently D5 domain is being mapped with the fine scale domain swapping. Results from this study will allow us to formulate a testable model that explains molecular mechanisms underlying dual-ligand selectivity of SPR.

Neuropeptide G protein coupled receptors in *Glossina morsitans*

Liliane Schoofs[1], Jelle Caers[2], Gerd Gade[3], Jan Van Den Abbeele[4], Stephan Tjonck[5], Heather Marco[6]

[1]KU Leuven, Belgium, [2]KU Leuven, Belgium, [3]University of Cape Town, South Africa, [4]Institute of Tropical Medicine Antwerp, Belgium, [5]KU Leuven, Belgium, [6]University of Cape Town, South Africa

The tsetse fly, Glossina morsitans, serves as a vector for protozoa of the species Trypanosoma brucei that cause African trypanosomiasis also called sleeping sickness, a parasitic disease of people and animals. The disease is endemic in some regions of sub-Saharan Africa, covering about 37 countries and 60 million people and leads to the death of ten thousands of people each year. The insects are less becoming susceptible to currently used insecticides due to increasing resistance. G protein coupled receptors (GPCRs) provide a potentially interesting target for the development of novel insecticides. We are annotating GPCRs and neuropeptides in the genome of Glossina and we are deorphanising the GPCRs for several neuropeptides, including adipokinetic hormone (AKH), allatostatins, pyrokinins, short and long neuropeptide F. Realtime PCR is used for spatial and developmental expression analysis of these GPCRs. Future experiments include reverse genetics in order to determine the physiological role of the GPCRs in Glossina.

Insect Immunology, Physiology and Neurobiology

Evolutionary plasticity of insect immunity

Andreas Vilcinskas

Justus-Liebig-University of Giessen Institute of Phytopathology and Applied Zoology, Germany

The rapidly increasing number of insect species which have been subjected to genome sequencing or to transcriptomic analysis of their innate immune responses invite comparative studies. From the molecular perspective, emergence of novel proteins or protein domains is foremost associated with adaptation to abiotic and biotic environmental stressors. The tremendous evolutionary plasticity of insect immunity is highlighted focusing on effector molecules such as antimicrobial peptides (AMPs) or proteinase inhibitors which display a higher evolutionary dynamic than, for example, immunity-related signaling molecules. Increasing evidence support the hypothesis that the functions of insect AMPs can be expanded beyond their role in defense against pathogens to include the management of beneficial endosymbionts. The total number of AMPs varies considerably in insects and provides intriguing examples for immune gene expansion and loss. This plasticity is discussed in context with recent developments in evolutionary ecology. Maintenance and deployment of immune responses allocates resources from other fitness-related traits and results in trade-offs. Based on our recent studies using both model and-non-model insects I postulate that loss of immune genes can occur in insects which evolved alternative and less fitness cost demanding defense strategies such as the so-called social immunity in bees, or the chemical sanitation of the microenvironment by some beetles. On the other hand, recent studies provide evidence for diversification and functional shifts of AMPs or defense-related proteinase inhibitors in insects which solely reflect coevolution with a changing pathosphere and/or adaptations to habitats or food associated with microbial contamination.

Virulence factors produced by pathogens provide important insights into the function of the insect immune system

Michael Strand
University of Georgia, U.S.A.

Insects rely upon a well-coordinated innate immune system for protection against foreign invaders. Among the most important natural enemies of insects are parasitoid wasps that carry polydnaviruses (PDVs). PDVs do not replicate in the wasp's host but expression of PDV-encoded genes cause physiological alterations that are essential for survival of the wasp's progeny. The most important of these alterations is immunosuppression. Genome analysis indicates that PDVs encode several genes of potential importance in immunosuppression while physiological studies identify several PDV-induced alterations in host immune defenses. Collectively, these data indicate the majority of the virulence factors encoded by PDVs target the signaling pathways that regulate host immune effector responses rather than effector molecules themselves.

Insect Immunology, Physiology and Neurobiology

Infection-induced physiological interaction between the mosquito circulatory and immune systems

Julian F. Hillyer
Vanderbilt University, U.S.A.

Mosquitoes respond to infection by mounting cellular and humoral immune responses. In the hemocoel, these responses are mediated primarily by hemocytes, which sequester and kill pathogens via phagocytic, lytic and melanization pathways. While much work has focused on the cellular biology of mosquito hemocytes, little is known about the in vivo dynamics of hemocyte-pathogen interactions in the insect hemocoel. Hemolymph currents disseminate invading pathogens to all regions of the hemocoel, and likewise, hemolymph currents propel hemocytes as they search for pathogens. This presentation will describe the temporal and spatial dynamics of hemocyte-pathogen interactions in the mosquito hemocoel, and will detail how hemocytes aggregate on the surface of the heart in response to infection. Using a novel method that stains Anopheles gambiae hemocytes in vivo, we found that mosquito hemocytes occur both in circulation and attached to tissues. Intravital video imaging then showed that infection with bacteria or malaria parasites induces the migration of circulating hemocytes to the periostial regions of the heart (regions adjacent to the heart valves), where they bind heart and alary muscles and engage in the phagocytosis of pathogens. Directed hemocyte migration to the periostial regions occurs in a time- and dose-dependent manner, with higher infection intensities inducing the aggregation of higher numbers of hemocytes. Together, these data describe the physiological interaction between the mosquito circulatory and immune systems, where hemocytes aggregate and phagocytose pathogens in the areas of highest hemolymph flow.

The impact of isoprenoid precursors released by parasites and pathogens on the immune response in *Drosophila* and *Anopheles*

Karolina Eriksson-Gonzales[1], Bo Lindberg[2], Olle Terenius[3], Makoto Hirai[4], Eleanor Merritt[5], Berit Olofsson[6], Ingrid Faye[7]
[1]Stockholm University, Sweden, [2]Stockholm University, Sweden, [3]Swedish University of Agricultural Sciences, Sweden, [4]Jichi Medical School, Japan, [5]RSC Publishing, United Kingdom, [6]Stockholm University, Sweden, [7]Stockholm University, Sweden

Isoprenoid precursors are small, non-peptidic compounds known to induce activation and massive proliferation of human Vγ2Vδ2 T-cells, which are important in killing malaria parasites.Little is known however about their effects in invertebrates. We have investigated the stimulating properties of isopentenyl pyrophosphate (IPP) and (E)-4-Hydroxy-3-methyl-but-2-enyl pyrophosphate (HMBPP) in malaria mosquito Anopheles gambiae. IPP is a universal isoprenoid precursor found in all living organisms. HMBPP is present in most eubacteria and in apicomplexan protozoa.It is the most potent Vγ2Vδ2 T-cells activator known with a bioactivity at picomolar concentrations. When HMBPP was provided in the blood meal to Anopheles gambiae,it induced the expression of immune and redox regulating genes in female mosquitoes. Also, HMBPP stimulation of A. gambiae4a3B cells, lead to activation of several signal transduction pathways that have earlier been implicated in human γδ T cell responses. HMBPP and IPP also increased 4a3Bcell tolerance to H2O2 induced oxidative stress.

The endosymbiont Wolbachia as an extension of the host antiviral immune system

Karyn N Johnson
The University of Queensland, Australia

Although single host-virus interactions are often studied in isolation, host organisms are typically infected by many microbe populations. Tripartite interactions between two microbes and the host can alter pathogenesis and disease outcome. In insects, the bacterium Wolbachia can protect the host against viral infection and viral-induced mortality. Drosophila is an important model system for understanding interactions between invertebrates and viruses. Remarkably, the extent of Wolbachia mediated antiviral protection in Drosophila is similar to the protection afforded by the host antiviral responses, indicating that the interaction between Wolbachia and virus has important biological implications. To explore the mechanism of antiviral protection, we investigated the importance of Wolbachia density within the insect host on antiviral protection. To do this, we used low doses of antibiotic to decrease the density of a protective Wolbachia strain in its natural host, to levels that were similar to those observed in two non-protective Wolbachia strains. Flies were then challenged with the pathogenic Drosophila C virus. It was found that when the density of the previously protective Wolbachia strain wAu was decreased to levels similar to the non-protective strains, Wolbachia-mediated antiviral protection was substantially decreased or lost completely. This data indicates that the density of Wolbachia in the insect host is important for the mechanism of antiviral protection and suggests that insects carrying a low load of Wolbachia will likely not be protected. These findings may facilitate prediction of Wolbachia-mediated protection in host-Wolbachia associations relevant for the biocontrol of insect-borne vir

Mosquito immunity to human pathogens

George Dimopoulos
Johns Hopkins University, Bloomberg School of Public Health, U.S.A.

Lacking the unlimited repertoire of antibodies provided by adaptive immunity, insects largely rely on their innate immune systems, involving a finite number (~400) of germ line-encoded immune genes, for their anti-pathogen defenses. Despite this limitation, insects can control infection by a great variety of parasites, microbes and viruses through immune deployment which largely is mediated by immune signaling pathways that control expression of anti-pathogen effector molecules. We have shown that the Aedes aegypti uses its Toll and JAK-STAT immune signaling pathways to combat dengue virus infection, while Anopheles mosquitoes use their IMD pathway to control infection with the human malaria parasite Plasmodium falciparum. We will present and discuss recently discovered and unexplored features and facets of mosquito innate immune defenses against human pathogens.

Biochemical characterization of host-immune related molecules by infection of pathogenic or symbiotic bacteria into the hemimetabolous insect, *Riptortus pedestris*

Bok Luel Lee
Pusan National University, Republic of Korea

To investigate the biochemical basis of how insects recognize invading pathogenic microbes and how pathogen recognition signals are transferred to the down-stream factors and activate host innate immune responses, it is necessary to use large insects, from which larger amounts of hemolymph can be extracted and can be used to perform biochemical studies. We have recently determined molecular activation mechanisms of insect's Toll signaling pathway after purification of several pattern recognition proteins, serine proteases, serpins and AMPs. In this talk, we will discuss the biochemical characterization of these molecules, which are involved in the recognition of pathogenic microbes, in the amplification of recognition signal transduction and in the regulation of proteolytic cascade leading to the production of AMPs in insects. Recently, we started the studies to elucidate the differences of molecular innate immunities, which are induced by pathogenic microbes or symbiotic bacteria. The model system used in this study is Riptortus pedestris (bean bug), belonging to the family Alydidae, which is well known pest of leguminous crops in eastern Asia. As symbiotic bacteria, we selected Burkholderia species. Burkholderia symbiotic bacteria specifically localized in the lumen of the midgut crypts. Prevalence of the Burkholderia infection was consistently high, 95?100%, in natural populations of the alydid stinkbugs. We purified several bean-bug specific AMPs and have characterized several genes that specifically expressed genes after Burkholderia infection in the mid-gut. We will discuss the molecular mechanisms of how hosts distinguish pathogenic bacteria and symbiotic bacteria in order to defense their bodies.

Bacterial flagellin as an initiator of insect immune responses

Stuart E Reynolds[1], Christophe Fleury[2]
[1]University of Bath, United Kingdom, [2]University of Bath, United Kingdom

Flagellin is recognised by the immune system of the model lepidopteran insect Manduca sexta. Recombinant flagellins from Salmonella enterica Typhimurium and Photorhabdus luminescens TT01 are effective inducers of insect immune reactions in vivo, a single injection causing large increases in the mRNA levels of several different antimicrobial peptide (AMP) genes, together with smaller increases in the mRNA levels of two pattern recognition receptor proteins (PRRs). Flagellin also causes prophenoloxidase (PPO) activation in cell-free M. sexta hemolymph in vitro, indicating that in this case, flagellin must be detected by a secreted PRR. Different regions of the Salmonella flagellin protein molecule are differentially effective in causing AMP expression and PPO activation, indicating that there is more than one flagellin recognition mechanism in this insect.

Organisation of the cuticle as a physical barrier involves the C-type lectin Schlaff

Khaleelulla Saheb Shaik[1], Frauke Meyer[2], Bernard Moussian[3]
[1]University of Tuebingen, Germany, [2]University of Tuebingen, Germany, [3]University of Tuebingen, Germany

The insect cuticle is an apical extracellular matrix produced by polarised epithelial cells. Distinct distribution of chitin, proteins, catecholamines and lipids leads to a stratified structure that assumes the multiple functions of the cuticle as a physical barrier and as an exoskeleton. The apical plasma membrane of these cells plays a central role not only as a passive interface for cuticle material deposition but also as an active organising performer. Concomitantly, extracellular processes are deployed for terminal cuticle assembly. In the past few years others and we have identified several membrane associated and extracellular factors that are essential for cuticle organisation and function. One of these factors in the fruit fly Drosophila melanogaster is Schlaff, a secreted C-type lectin that we have shown to bind to mannose and N-acetylglucosamine. It localises to the basal site of the cuticle adjacent to the apical plasma membrane. Elimination of Schlaff function causes loosening of cuticle layers, and mutant animals suffer massive water loss. Intriguingly, removal of Schlaff within the imago head abrogates Ptilinum integrity, whereas hard cuticle parts appear to remain stable. We therefore hypothesise that Schlaff is needed to establish a physical barrier especially within soft cuticle (larval cuticle, Ptilinum) that antagonises the internal hydrostatic pressure. Since orthologuous sequences are present in other insects as well, this function is probably not confined to D. melanogaster. Further analyses of the Schlaff protein should reveal the molecular network of its activities.

Cuticular hydrocarbon biosynthesis

Rene Feyereisen[1], Yue Qiu[2], Claus Tittiger[3], Claude Wicker-Thomas[4], Gaelle Le Goff[5], Sharon L. Young[6], Gary J. Blomquist[7]
[1]INRA, France, [2]University of Nevada, U.S.A., [3]University of Nevada, U.S.A., [4]CNRS Universite de Paris Sud, France, [5]INRA, France, [6]University of Nevada, U.S.A., [7]University of Nevada, Reno, U.S.A.

Insects use hydrocarbons as cuticular waterproofing agents and as contact pheromones; however the last step of alkane biosynthesis from long chain fatty aldehydes has remained mysterious. Unlike cyanobacteria that make alkanes from aldehydes with a non-heme diiron decarbonylase, we show here that insects use a P450 enzyme of the CYP4G family to oxidatively produce terminal hydrocarbons from aldehydes. Oenocyte-directed RNAi knock-down of Drosophila CYP4G1 or NADPH-cytochrome P450 reductase both result in flies deficient in cuticular hydrocarbons and highly susceptible to desiccation or that die upon adult emergence. The heterologously expressed enzyme converts C18-trideuterated octadecanal to C17-trideuterated heptadecane, showing that the insect enzyme is an oxidative decarbonylase that catalyzes a novel cleavage of long chain aldehydes to alkanes and carbon dioxide. The highly conserved CYP4G enzymes of insects are a key evolutionary innovation that allowed their colonization of land.

Cuticular hydrocarbons and behaviour in social insects

Judith Ingrid Dr Korb
University of Osnabrueck, Germany

Social insects (ants, termites and some bees and wasps) live in complex societies which are mainly coordinated through chemical communication. Especially cuticular hydrocarbons (CHC) seem to be involved in species identification, nestmate recognition, and status communication within colonies. The latter two are particular important as they ensure that altruistic behaviour is directed towards relatives and that colonies have few conflicts. The 'reproductive harmony' in social insects, expressed in the queen's reproductive monopoly, is often maintained via CHCs on the queen's cuticle that reveal her fertility to the non-reproductive workers. There has been fundamental progress in uncovering how CHCs function in insect societies. I will provide an update on this progress and present results for a termite species where the underlying molecular process of royalty signalling has been studied in detail. Using a combination of RNA interference, behavioural assays, endocrinological studies and chemical analyses we could identify a gene involved in the production of the queen's royalty scent in the lower termite Cryptotermes secundus. The expression of this gene, Neofem4, seems to be positively regulated by juvenile hormone. This makes Neofem4, a cytochrome P450 gene, a reliable indicator of the queen's fertility.

Molecular basis of color pattern formation in dragonflies

Ryo Futahashi[1], Takema Fukatsu[2]

[1]National Institute of Advanced Industrial Science and Technology, Japan, [2]National Institute of Advanced Industrial Science and Technology, Japan

Because dragonflies visually recognize conspecific and heterospecific individuals, their body color plays essential roles in their ecology and reproductive biology. Unlike most insects, some dragonflies change their body color dramatically upon sexual maturation. While many ecological and behavioral studies have been focused on this topic, molecular mechanisms underlying the color pattern formation have been poorly understood. Here we report our recent findings on molecular basis of color pattern formation in dragonflies. We analyzed pigments and genes that are involved in the different color patterns in dragonflies. Melanins, ommochromes, and pteridines represent the major pigment groups found in dragonflies. Notably, we found that sex-specific redox changes in ommochrome pigments cause the yellow-red color transition in some dragonflies, which unveils a previously unknown molecular mechanism underlying body color change in animals. We also identified several genes associated with different color patterns in dragonflies, which suggests that different molecular mechanisms are involved in the color pattern formation in different dragonfly lineages.

Wing pigment patterns in the ladybird beetle, *Harmonia axyridis*

Teruyuki Niimi
Nagoya University, Japan

Insect wing color patterns demonstrate a tremendous range of diversity and have evolved to fulfill various ecologically important functions such as intraspecific sexual signaling, mimesis, mimicry and warning against predators. The molecular mechanisms behind such pattern formation, however, remain unknown. To investigate the developmental mechanisms of color pattern formation, we chose the multicolored Asian ladybird beetle, Harmonia axyridis (Coleoptera), which has conspicuous and variable wing color patterns consisting of black and red pigments. Classical genetic studies revealed that the elytral color patterns are thought to be regulated by a single locus which gives multiple alleles, and that the color patterns are formed from the superimposition of any combinations of four major alleles. In addition, in any heterozygotes, the black-pigmented area invariably appears as dominant character at the overlapping black and red pigmentations where the color patterns of different alleles are superimposed. The mechanisms involved in wing color pattern formation remain unknown. As an initial step to understand the mechanisms, we examined histologically and biochemically the pigmentation of H. axyridis wing. Our observations suggest that carotenoids only localize in the region where no melanization occurs, and that melanin synthesis depends on dorsal cells, whereas carotenoids are accumulated in ventral cells. To elucidate the molecular mechanisms underlying the wing color patterns, we have established a technique for RNA interference (RNAi) in the ladybirds. We will report our progress in the expression and functional analyses of melanin-synthesis enzymes during wing development.

Relationship of cuticular proteins and sclerotization with mechanical properties of beetle cuticle

Michael R Kanost[1], Neal T Dittmer[2], Yasuyuki Arakane[3], Patricia A. Sprouse[4], Joseph Lomakin[5], Stevin H Gehrke[6], Subbaratnam Muthukrishnan[7], Richard W Beeman[8], Karl J Kramer[9]

[1]Kansas State University, U.S.A., [2]Kansas State University, U.S.A., [3]College of Agriculture and Life Science, Chonnam National University, Republic of Korea, [4]University of Kansas, U.S.A., [5]University of Kansas, U.S.A., [6]University of Kansas, U.S.A., [7]Kansas State University, U.S.A., [8]Agricultural Research Service, United States Department of Agriculture, U.S.A., [9]Agricultural Research Service, United States Department of Agriculture, U.S.A.

Insect cuticle is composed primarily of chitin, proteins, and catechol metabolites of tyrosine. Chitin fibers are embedded in a matrix of cuticular proteins, with additional stability provided through cross-links with catecholic molecules (sclerotization). The oxidized products of catechols also can polymerize to form the pigment melanin. The physical properties of cuticle can vary from hard and rigid to soft and flexible and from transparent to highly pigmented. We are using genomic information from the red flour beetle, Tribolium castaneum, for experiments aimed at understanding how variation in the cuticular protein composition and the metabolism involved in sclerotization and pigmentation affect cuticle properties using wings as model tissues. The forewings of beetles are modified to form heavily sclerotized elytra, which function as a protective covering, whereas the hindwings used for flight are formed from a flexible, membranous cuticle. Thus, the elytra and hindwings are two developmentally related structures that offer the possibility of examining both hard and flexible cuticles. We have analyzed the gene products present in elytra and hindwings by microarray and proteomics experiments. We observed preferential expression of RR-2 cuticular proteins in the elytra and RR-1 proteins in the hindwings. Elytra are also enriched in cuticular proteins with low sequence complexity. Two RR-2 cuticular proteins are highly abundant in elytral cuticle. RNAi experiments indicate that these two structural proteins are essential for morphogenesis of the elytra. Genes involved in catechol metabolism related to sclerotization and pigmentation also affect the mechanical properties of elytra. (Supported by NSF grant IOS0726425)

RNAi-based functional analysis of yellow-e in *Tribolium castaneum*

Mi Young Noh[1], Michael R Kanost[2], Subbaratnam Muthukrishnan[3], Richard W Beeman[4], Karl J Kramer[5], Yasuyuki Arakane[6]

[1]Chonnam National University, Republic of Korea, [2]Kansas State University, U.S.A., [3]Kansas State University, U.S.A., [4]USDA-ARS, U.S.A., [5]USDA-ARS, U.S.A., [6]Chonnam National University, Republic of Korea

Yellow protein (dopachrome conversion enzyme, DCE) is involved in the melanin biosynthetic pathway and significantly accelerates pigmentation and melanization reactions. Recent studies have suggested that yellow is a rapidly evolving gene family generating functionally diverse paralogs. However, the exact physiological functions of several yellow genes are still not understood. Injection of dsRNAs for Tcyellow-e (TcY-e) into last instar larvae had no effect on larval-pupal molting, and the resulting pupae developed normally. The pupal cuticle (e.g. setae, gin traps and urogomphi) showed normal tanning. Adult cuticle could also be viewed through the translucent pupal cuticle. Adult cuticle tanning (e.g. head, mandibles and legs) was initiated on schedule, indicating that TcY-e is not required for pupal or adult cuticle pigmentation in T. castaneum. The subsequent pupal-adult molt, however, was adversely affected. Although pupal cuticle apolysis and slippage were evident, some of the adults (~20%) were unable to shed their exuvium and died entrapped in their pupal cuticle. In addition, the resulting adults rapidly became completely desiccated. Failure of the pupal-adult molt and desiccation-induced mortality were prevented by maintaining dsRNA TcY-e-treated insects at 100% relative humidity (rh). When the humidity-rescued adults were subsequently moved from 100% rh to 50% rh, they quickly desiccated and died (wild-type insects thrive throughout development at 50% rh). Immunolocalization studies revealed the presence of TcY-e in the adult hard cuticle. These results suggest that TcY-e has a "critical waterproofing" function for cuticle rather than cuticle pigmentation. This work was supported by NRF (20110029585).

Laccase activation in ecdysis process

Tsunaki Asano
Tokyo Metropolitan University, Japan

Laccase is a multi-copper protein found in various organisms. In insects, laccase participates in cuticle formation by oxidizing phenolic compounds to generate highly reactive products which contribute to sclerotization and coloration of the cuticle. When synthesized beneath the old cuticle, the new cuticle is initially soft and colorless, but later becomes hardened and pigmented at specific time points during ecdysis. The completion of this process requires precise regulation of laccase activity in the newly synthesized cuticle. With the aim of elucidating the mechanisms underlying the sclerotization process, the molecular properties and expression pattern of laccase2 of the silkworm, Bombyx mori were studied. Transcripts of laccase2 (Bmlac2) are abundant before pupal ecdysis, and Bmlac2 protein accumulates at this stage of pupal cuticle formation. However, little laccase activity is detectable in the cuticle by in situ staining. Laccase activity becomes detectable only after pupal ecdysis. This observation suggests that laccase is present in the newly synthesized pupal cuticle as an inactive precursor that is activated after pupal ecdysis. An inactive form of Bmlac2 can be solubilized from the cuticles of newly ecdysed pupae by treatment of cuticles with α-chymotrypsin. The inactive Bmlac2 was purified to homogeneity as judged by SDS-PAGE. The purified laccase can be converted to active enzyme by treatment with proteases or buffered isopropanol, suggesting that the Bmlac2 precursor can be activated in vivo. The mechanisms involved in such putative activation remain unknown.

Keywords:*laccase*

Functional analysis of chitin-binding proteins in the cuticle of *Tribolium castaneum*.

Subbaratnam Muthukrishnan[1], Sinu Jasrapuria[2], Sujata Chaudhari[3], Beibei Li[4], Yasuyuki Arakane[5], Bernard Moussian[6], Hans Merzendorfer[7], Charles A. Specht[8], Richard W. Beeman[9], Karl J. Kramer[10]

[1]Kansas State University, U.S.A., [2]Kansas State University, U.S.A., [3]Kansas State University, U.S.A., [4]Kansas State University, U.S.A., [5]Chonnam National University, Japan, [6]University of Tubingen, Germany, [7]University of Osnabrueck, Germany, [8]University of Massachusetts medical School, U.S.A., [9]USDA-ARS, CGAHR, U.S.A., [10]Kansas State University and USDA-ARS, CGAHR, U.S.A.

An extensive bioinformatics search of the genome of the red flour beetle (T. castaneum) has identified genes encoding >50 proteins with the peritrophin A domain (ChtBD2), an ~65 amino acids-long sequence motif with its characteristically spaced set of six cysteines. Among these we have identified two families of genes encoding proteins that have one and three ChtBD2 repeats, which we have named cuticular proteins analogous to peritrophins, CPAP1 and CPAP3. The genome also encodes >100 proteins with the ~65 amino acids-long Rebers & Riddiford chitin-binding motif devoid of cysteines. We have also identified two other genes Knickkopf and Retroactive, which have been implicated in cuticle organization. All of these genes are uniquely expressed in cuticle forming tissues, but not in the gut. The individual members of the CPAP1 and CPA3 families differ in their expression patterns during development suggesting distinct functions. This was confirmed by RNA interference (RNAi) of specific members of these two families of genes. These studied have revealed functional specialization even among members of the same family. The phenotypes resulting from these RNAi experiments include molting arrest, reduction in chitin content, elytral, wing and joint abnormalities, loss of fecundity and defective egg hatch. Knickkopf and retroactive are involved in protecting and organizing chitin into laminae in the cuticle. The conservation of orthologs of these genes in different orders of insects suggest that they serve essential and non-redundant functions that affect cuticles in various parts of the insect anatomy and at distinct stages of development.

Chitin synthesis inhibitors: Old molecules and new developments

Hans Merzendorfer
University of Osnabruck, Germany

During the past decades, a larger number of chemically unrelated insecticidal compounds have been developed and commercialized that interfere with chitin biosynthesis, a process which is essential to growth and development of arthropods. Common symptoms after administration of these compounds are abortive molting and defects in egg hatching. Some of them are also effective in disrupting the barrier function of the peritrophic matrix. Chitin synthesis inhibitors are chemically diverse and include compounds such as pyrimidine-nucleoside peptides, benzoylureas, oxazolines and thiazolidinones. Pyrimidine-nucleoside peptides act as competitive inhibitors at the catalytic site of the chitin synthase, a membrane bound glycosyltransferase, which is considered the key enzyme of the chitin biosynthetic pathway. However, many of the commercialized acaricides and insecticides act at a post-catalytic step of chitin synthesis. Their mode of action has remained largely elusive. In a genomic and proteomic study we used Tribolium castaneum as a model for investigating the insecticidal effects of the benzoylurea compound, diflubenzuron. The results of this study recapitulate all of the different diflubenzuron-induced symptoms in a single model insect, which have been previously found in several different insect species, and further illustrate that diflubenzuron-treatment causes a wide range of effects at the molecular level. Recent progress in understanding the mode of action of the oxazoline compound, etoxazole, suggests that this chitin synthesis inhibitor targets directly the chitin synthase at a post-catalytic site, which could impair translocation of the nascent chitin chain across the membrane or oligomerization of single chitin synthase subunits.

Peptidergic signaling cascades in regulation of insect ecdysis

Michael Edward Adams[1], Do-Hyoung Kim[2], Dusan Zitnan[3]
[1]University of California, Riverside, U.S.A., [2]University of California, Riverside, U.S.A., [3]Slovak Academy of Sciences, Slovakia

Molting and ecdysis are distinctive and characteristic features of arthropod physiology and vital for growth and metamorphosis from juvenile to adult. These developmental and behavioral events are regulated by steroid and peptide hormones. Early in the molt, elevated ecdysteroid levels induce expression of genes important for scheduling tracheal dynamics and behavioral steps leading to ecdysis. These include the ecdysis triggering hormone (ETH) precursor gene in endocrine Inka cells and the ETH receptor gene (ETHR) expressed in sets of identified central neurons. Inka cells accumulate large amounts of ETH peptides during the molt, but acquire competence to release only shortly before ecdysis following expression of the late gene β-FTZ-F1. ETH release into the hemolymph initiates tracheal inflation, followed by pre-ecdysis, ecdysis, and post-ecdysis behaviors. These behaviors coincide with ETH activation of central peptidergic ensembles that release FMRFamides, eclosion hormone, kinins, CCAP, MIPs, and bursicon. Successive release of these peptides into the CNS and periphery activates central pattern generators that drive sequential behaviors. We are examining the roles played by these neurons in behavioral scheduling using genetics and physiological manipulations. Our findings offer insights into how peptidergic neural circuits regulating behaviors are assembled and activated.

The proctolin gene and actions of proctolin in the blood-feeding bug, *Rhodnius prolixus*

Angela B Lange[1], Do Hee Lee[2], Ian Orchard[3]

[1]University of Toronto Mississauga, Canada, [2]University of Toronto Mississauga, Canada, [3]University of Toronto Mississauga, Canada

Proctolin was the first insect neuropeptide to be sequenced and synthesized, and appears to be unique to arthropods. The proctolin gene has, however, only been found in the genomes of a few insect species, including Drosophila melanogaster, Tribolium castaneum, Tenebrio molitor, and Acyrthosiphon pisum. No proctolin gene has been identified in genomes of Apis mellifera, Aedes aegypti, Bombyx mori, Nasonia vitripennis, or Acromyrex echinatior and 3 other ant species, where proctolin and its receptor are now considered absent. A recent study on neuropeptides in Rhodnius prolixus failed to identify a proctolin gene, and it was suggested that R. prolixus also lacks proctolin (Ons et al., 2011, Insect Molecular Biology 20, 29-44). We have reinvestigated the possible absence, or in fact, presence of the pentapeptide proctolin in the Chagas' disease vector, R. prolixus. Here we report the cloning of the proctolin cDNA, and find the transcript to be expressed in the central nervous system (CNS) and some peripheral tissues. A single copy of proctolin is predicted to be processed from the prepropeptide. We have biochemically identified proctolin in CNS extracts and shown its distribution using proctolin-like immunoreactivity (PLI). PLI is found in processes on the salivary glands, male and female reproductive tissues, and heart and associated alary muscles. Proctolin-like immunoreactive bipolar neurons are found on the lateral margins of the common oviduct and bursa. Proctolin stimulates increases in contractions of anterior midgut and hindgut muscles, and increases heartbeat frequency. Proctolin is indeed present and biologically active in this medically-important bug.

The brown planthopper, Nilaparvata lugens (Stal), is one of the most problematic insect pests of rice in Asia. The understanding of neuropeptide-signaling in N. lugens may enable the design of a new insecticide that resolves the problem of resistance to various insecticides since the insecticide targeting neuropeptide-related genes has not been developed so far. We have identified neuropeptide genes and G protein-coupled receptors (GPCRs) for neuropeptides comprehensively by combining homology search in the genome sequence and in RNA-seq data with cDNA cloning. N. lugens has the highest number of neuropeptide precursor genes compared to other insects with fully sequenced genomes. The genes encoding prothoracicotropic hormone (PTTH), inotocin, and their receptors were identified in N. lugens although these genes had not been identified in the other hemimetabolous insects. An orphan GPCR homologous to vertebrate parathyroid hormone receptor was identified in N. lugens. This gene has orthologs in several insect species but the function remains to be known. RNA interference (RNAi) of several neuropeptide and GPCR genes, e.g., PTTH and adipokinetic hormone receptor (AKHR), resulted in the disruption of development although the knockdown of these genes have not been reported to cause mortality in other insects. This result suggests that the physiological importance or function of structurally related neuropeptides is diverse among insects.

Diuretic and anti-diuretic strategies in the blood-gorging bug, *Rhodnius prolixus*

Ian Orchard
University of Toronto Mississauga, Canada

Serotonin is a diuretic hormone in R. prolixus, but there is also ample evidence for the presence of a peptidergic diuretic hormone. The identity of this peptide has remained elusive; but recently, using molecular techniques and mass spectrometry, we have sequenced the peptidergic diuretic hormone and find it to be a member of the CRF-related family of insect neuropeptides. Rhopr-CRF/DH has potent biological activity on anterior midgut and Malpighian tubules, and works synergistically with serotonin during rapid post-feeding diuresis in R. prolixus. Cardioacceleratory peptide 2b (CAP2b) belongs to a family of neuropeptides (now referred to as CAPA peptides) that can serve diverse roles in the regulation of water and salt homeostasis in insects. These peptides stimulate fluid secretion by Malpighian tubules in dipterans, thus serving a diuretic function, whereas they have an anti-diuretic role in R. prolixus and some other hemipterans. We have identified two paralog genes which encode Rhopr-CAPA peptides, and also identified the G protein-coupled receptor that is activated by one of these peptides, Rhopr-CAPA-2. This anti-diuretic peptide and cognate receptor are important mediators in the cessation of rapid post-feeding diuresis in R. prolixus, inhibiting serotonin-stimulated secretion by Malpighian tubules, but not, apparently, Rhopr-CRF/DH-stimulated secretion. Rhopr-CAPA-2 appears to prevent the synergism between the diuretic hormones serotonin and Rhopr-CRF/DH. The interplay between diuretic and antidiuretic hormones in R. prolixus results in a remarkable diuresis; a diuresis that has evolved to eliminate excess water and salts from a massive blood meal, whilst maintaining homeostasis within the haemolymph.

Evolution of family-B GPCRs in insects and its function in *Tribolium castaneum*

Chengjun Li[1], Ming Sang[2], Xing Liu[3], Bin Li[4]

[1]Nanjing Normal University, China, [2]Nanjing Normal University, China, [3]Nanjing Normal University, China, [4]Nanjing Normal University, China

Family-B of G protein-coupled receptors (GPCRs) is associated with the regulation of circadian rhymicity, water and ion balance, lifespan and reproduction and other biological processes. However, it was less focused in the past years. Taking advantage of the recently sequenced insect genomes, we performed a genome-wide analysis of family-B GPCRs through 6 insects by using known GPCRs as references. Totally, we have identified 64 family-B GPCRs, 20 from Tribolium castaneum, 11 from Apis mellifera, 9 from Bombyx mori, 9 from Acyrthosiphon pisum, 14 from Anopheles gambiae and 1 novel member from Drosophila melanogaster. The result suggests that they are of ancient origin and have evolved through gene duplication/lost events. Phylogenetic and gene structure analysis have revealed 3 primary kinds of evolutionary patterns of family-B GPCRs during its evolution. Furthermore, the function and signal transductions of family-B GPCRs have been characterized in Tribolium castaneum by RNAi and high throughput methods, this work will provide a framework of information on family-B GPCRs of Tribolium and other non-drosophiline insect. It will significantly promote the functional analysis of family-B members.

Bursicon homodimers induce immune gene expression

Qisheng Song
University of Missouri, U.S.A.

Bursicon is a heterodimer neuropeptide composed of two cystine knot proteins, bursicon α (burs α) and bursicon β (burs β), that elicits cuticle tanning (melanization and sclerotization) through the Drosophila leucine-rich repeats containing G protein-coupled receptor 2 (DLGR2). Recent studies show that both bursicon subunits also form homodimers. However, biological functions of the homodimers remain unknown. Using recombinant bursicon protein, we have shown in Drosophila melanogaster that both bursicon homodimers induced expression of genes encoding antimicrobial peptides (AMPs) in neck-ligated adults following recombinant homodimer injection and in larvae fat body after incubation with recombinant homodimers. Up-regulation of AMP genes by the homodimers was accompanied by reduced bacterial populations in fly assay preparations. The induction of AMP expression is via activation of the NF-κB transcription factor Relish in the immune deficiency (Imd) pathway. These results reveal a mechanism of CNS-regulated prophylactic innate immunity during molting via induced expression of AMPs.

Molecular physiology of tick salivation

Yoonseong Park
Kansas State University, U.S.A.

Ticks are obligatory ectoparasites causing global animal and human health problems. Ticks transmit a wide variety of pathogens, while they also directly damage the host. Nervous control of the salivary gland in tick is a critical step in blood feeding, since it is required for activation of salivary secretion and osmoregulation during blood feeding. While previous studies identified dopamine and arachidonic acid as compounds that activate salivary secretion, our recent finding indicates presence of more complex mechanisms for control of the salivary glands. We identified at least two neuropeptides, myoinhibitory peptide and SIFamide, innervating the salivary glands in blacklegged ticks (Ixodes scapularis Say) which transmits the most important tick-born disease Lyme disease. We hypothesize that these neuropeptides control dopaminergic cells located on the base of acini in the salivary glands. The fundamental knowledge obtained from this research is eventually expected to lead to the design of compounds and vaccines to prevent disease transmissions by ticks.

Mechanisms that underlie learning and memory of complex floral odors by honey bees and moths

Brian H Smith[1], Fernando F Locatelli[2], Patricia C Fernandez[3]

[1]Arizona State University, U.S.A., [2]Facultad de Ciencias Exactas y Naturales, Universidad de Buenos Aires, IFIByNE (UBA CONICET), Argentina, [3]Rio Parana de las Palmas y Canal Comas, Argentina

Flower odors are highly variable combinations of several volatile components. No two flowers smell exactly alike.. Honey bees must therefore establish if a newly encountered flower is similar enough to a previous rewarded one, turning foraging decisions into a fine tuned generalization-discrimination problem. Sensory and neural systems must provide mechanisms for very precise odor recognition, allowing for perceptual stability. We hypothesize that experience with odors tunes sensory processing and thereby improves odor recognition and classification of newly encountered flowers. To test this hypothesis, we have designed artificial floral blends that mimic the components, proportions and variability of two natural varieties of snapdragon flowers. All designed blends share the same components. But they can be differentiated based on the relative concentration of the components, which were more similar within than between cultivars. Bees were differentially conditioned using examples of both cultivars. After training we tested the ability to recognize a new example from each cultivar. The duration of PER was lower and the latency longer when an example of the non-rewarded cultivar was offered to the trained bee. Odor induced activity patterns were measured in Projection Neurons of the Antennal Lobe by calcium imaging . Consistent with behavior, results suggest that the neural network in the AL is tuned via differential conditioning to decorrelate mixtures representing different floral varieties. Experience-dependent plasticity at the level of the Antennal Lobe may help animals categorize a newly flower as belonging to a class related to reinforcement.

Representation of behaviorally relevant odor information in the *Drosophila* brain

Bill S Hansson[1], Antonia Strutz[2], Jawaid Ahsan[3], Silke Sachse[4], Markus Knaden[5]

[1]Max Planck Institute for Chemical Ecology, Germany, [2]Max Planck INstitute for Chemical Ecology, Germany, [3]Max Planck INstitute for Chemical Ecology, Germany, [4]Max Planck INstitute for Chemical Ecology, Germany, [5]Max Planck INstitute for Chemical Ecology, Germany

Insects must decide how to react to detected olfactory stimuli based on complex input. The fruit fly Drosophila melanogaster evaluates food sources based on such cues. We used a bioassay to establish the innate valence of 110 odorants in the fruit fly. We analyze neuronal activation patterns evoked by attractive and aversive odorants and show that even though the identity of odorants is coded by the set of activated receptors, the main representation of odorant valence is formed at the output level of the antennal lobe. The topographic clustering within the antennal lobe of valence-specific output neurons resembles a corresponding domain in the olfactory bulb of mice. The basal anatomical structure of the olfactory circuit between insects and vertebrates is known to be similar; our study suggests that the representation of odorant valence is as well.

From sensory receptors to functional neural networks: Constructing and deconstructing olfactory circuits in *Drosophila*

Pelin Cayirlioglu Volkan
Duke University, U.S.A.

Insects detect volatile chemicals in their environment via olfactory receptors expressed on the surface of olfactory receptor neurons (ORNs). There are three receptor gene families that were shown to function in Drosophila olfaction: odorant receptors (ORs), ionotropic glutamate receptors (IRs) and gustatory receptors (GRs). In the Drosophila olfactory system, 1200-1300 ORNs, housed in clusters of 1-4 cells within olfactory sensilla on the antenna and the maxillary palps (MP), are specified to generate 50 different ORN classes. Each ORN class is defined by the exclusive expression of generally one olfactory receptor gene from a large genomic repertoire and their class-specific connectivity in the brain. How ORNs are specified and choose to express a single olfactory receptor gene remains an unanswered question. As the ORNs in the same sensilla develop from the same olfactory precursor cells, the sensory receptor potential of the pluripotent precursor cells is a critical determinant of the olfactory receptor expression by ORNs in each sensillum. Sequential restriction of sensory receptor potential of precursor cells can be achieved spatio-temporally during development, determining the specific receptor subsets to be expressed in specific sensilla. We have been investigating the role of transcription factors that regulate specification and olfactory receptor expression by ORN classes at the level of the precursor cells and epigenetic networks that function at the level of individual ORNs. The results from these studies will be discussed.

Introceptive sugar sensing in *Drosophila*

Greg Suh[1], Monica Dus[2], Soohong Min[3]

[1]Skirball institute, NYU School of Medicine, U.S.A., [2]Skirball institute, NYU School of Medicine, U.S.A., [3]Skirball institute, NYU School of Medicine, U.S.A.

In past 30 years, there has been a dramatic increase in obesity around the world. This growing obesity pandemic is at least in part ascribed to poor eating habit. However, because eating behavior is influenced by multiple factors such as nutritional needs and food palatability, it has been difficult to investigate how this behavior is regulated. Peripheral chemosensory neurons such as sugar receptor neurons endow animals with the ability to detect palatable food. Additional mechanisms would exist for the detection of foods that meet nutrient needs. Indeed, my laboratory showed that the Drosophila mutants- GR5a;GR64a and pox-neuro mutants- that are insensitive to the taste of sugar still developed a preference for a sugar solution based on its nutritional value after prolonged periods of food deprivation. These findings suggest that there exists a taste-independent, internal sugar sensor that detects its caloric content. Using this two-choice preference assay (D-glucose versus non-metabolizable L-glucose), we carried out a small-scale screen for an internal sugar sensor and identified a mutation in a Na+/Glucose co-transporter, dSGLT11, that was completely insensitive to the caloric content of sugar, but rather responded only to the concentration of sugar- the "sweetness". Intriguingly, tissue specific knock-down of dSGLT11 specifically in the nervous system caused the dSGLT11 mutant phenotype. Consistent with this, dSGLT11 is expressed in few regions of the brain including the antennal lobe, the subesophageal ganglion, and the central complex. This restricted expression pattern postulated a hypothesis that dSGLT11 functions as a glucose sensor instead of a mere glucose transporter.

The speed of smell: Odor-object segregation within milliseconds

Paul Szyszka[1], Jacob Stierle[2], Stephanie Biergans[3], C Giovanni Galizia[4]

[1]University of Konstanz, Germany, [2]University of Konstanz, Germany, [3]University of Konstanz, Germany, [4]University of Konstanz, Germany

Segregating objects from background has been investigated in depth in vision and audition (figure-ground segregation, cocktail party effect) but has hardly been investigated in olfaction. Natural olfactory stimuli fluctuate at fast timescales, and it is not known whether and, if so, how animals use this temporal information to segregate concurrent odor-objects from independent odor sources. We addressed this issue by combining behavioral and physiological experiments in honeybees. We asked whether honeybees can use short temporal differences between two components of a binary odorant mixture to extract information about its components. We first trained honeybees to respond to an odorant A by pairing A with a sugar reward. Then, we tested memory retrieval with a mixture of A and a novel odorant B. We found that a 6 ms asynchrony in the onset of A and B is sufficient to enhance the salience of the component odor information, and that it is not necessary that the component in question was presented alone at any time during the stimulus. We then searched for a neural mechanism of odor-object segregation and asked whether olfactory projection neurons in the antennal lobe are influenced by short time delays in odor component onsets in mixtures. Using in vivo calcium imaging we found that the processing of temporally incoherent mixtures with 5 to 600 ms odor-onset delays between the components involved more inhibitory interactions than the processing of coherent mixtures.

Plastic control of olfactory pheromone responses in *Drosophila*

Aki Ejima
Kyoto University, Japan

How does an animal extract salient information from its complex and variable environment? In fruit fly, Drosophila melanogaster, cis-vaccenyl acetate (cVA), a product of the male ejaculatory bulb, works as a courtship inhibitory pheromone. Previously we found that a male was capable to detect tiny amount of cVA and decreased his courtship motivation. However, it was unclear how the male could detect such a tiny amount of exogenous cVA without disruption by his own self-produced cVA. In this study, we predicted that olfactory sensitivities were constantly adjusted by the pheromonal environment to allow a male to ignore his own smell and focus on novel stimuli, and performed physiological analysis using a neural activity marker and behavioral analysis coupled by genetic manipulation using RNAi. First we found that prolonged exposure to purified cVA caused an enhanced level of subsequent courtship activity. This indicated the presence of homeostatic modulation, in which artificial activation of courtship inhibitory pathway increased basal activities and/or sensitivities of the counterpart courtship stimulatory pathway. Blocking the cholinergic excitatory input to the presynaptic terminals of the sensory neurons completely diminished this experience-dependent sensory modulation, suggesting that acetylcholine played a critical role for lateral communication between two groups of pheromone pathways and maintenance of signal equilibrium between them for precise pheromone coding.

Specialized noses for specialized lifestyles

Marcus Carl Stensmyr
Max Planck Institute for Chemical Ecology, Germany

The olfactory system directly interfaces with the environment, thus, changes in the environment, or a change in an animal's habits, as e.g. specialization, would presumably also lead to changes in the olfactory system. Comparative studies on specialized animals, with known generalist ancestors, could hence be a way of revealing general processes shaping olfactory systems, as well as highlighting importance and function of specific chemosensory genes. In this presentation I will outline current work in our laboratory dealing with olfactory adaptations at the molecular, physiological, morphological and behavioral level in a set of highly specialized drosophilid flies.

Evolution of the insect chemoreceptor superfamily

Hugh M. Robertson
University of Illinois at Urbana-Champaign, U.S.A.

The insect chemoreceptor superfamily are ligand-gated ion channels that serve as gustatory and olfactory receptors. It is divided into two families phylogenetically. The ancestral GR family of largely gustatory receptors can now be traced back through animal evolution, including Mollusca, Annelida, and Nematoda, as well as basal deuterostomes, to Cnidaria and Placozoa, but was lost in Chordata. The OR family of odorant receptors clearly evolved from within the GRs, apparently as a specialization for terrestriality in insects, because the other three arthropods with genome sequence (Daphnia, tick, and centipede) do not have ORs. Within the insects, the repertoire size of ORs and GRs is generally concordant with the known complexity of chemical ecology of the insect, ranging from small in human body louse to large in ants. Recent results include a reduction of the OR and GR families in the tsetse fly, reduction of GRs but expansion of ORs in the hessian fly, and modest expansion of these families in a termite, which instead has a large expansion of the unrelated IR (ionotropic receptor) family of candidate gustatory and olfactory receptors.

Optophysiological approaches to olfactory signal transduction and odor processing in larval *Drosophila*

Andre Fiala[1], Ulrike Pech[2], Atefeh Pooryasin[3]

[1]Georg-August-University of Goettingen, Germany, [2]Georg-August-University of Goettingen, Germany, [3]Georg-August-University of Goettingen, Germany

Olfactory signal transduction and odor processing in insects is subject to intense research. In Drosophila, olfactory signal transduction depends on the co-expression of a specific odorant receptor and the non-specific Or83b co-receptor (Orco). Recent studies suggested the generation of a receptor potential via a second messenger independent pathway [1]. However, an additional involvement of the second messenger cAMP has been proposed [2]. We use optogenetic techniques in combination with behavioral analysis to investigate molecular components for olfactory signal transduction in Drosophila larvae. Through the expression of a light sensitive adenylate cyclase (Pacα) [3] in OSNs cAMP levels can be artificially increased through light stimulation. As has been shown previously [4], we observed that a positive chemotaxis can be induced by light stimulation. In the absence of endogenous Orco, the Pacα-induced behavioral response is largely abolished, indicating that cAMP affects olfactory signaling and that Orco is a target of cAMP. On the contrary, when larval OSNs were activated using channelrhodopsin-2 a light-induced positive taxis behavior was observed with or without Orco. Based on these results we use calcium imaging to visualize odor-induced and light-induced activity of larval olfactory neurons and investigate possible functional implications of cAMP within the larval olfactory signal transduction system. A microRNA-based screen for novel genes involved in olfactory physiology

Walton D. Jones
KAIST, Republic of Korea

Insects use their olfactory systems to find food and mates and to avoid danger. The behavioral responses to these important external cues are guided by subpopulations of olfactory sensory neurons (OSNs) that express receptors that recognize behaviorally relevant volatile odorants. Although the role of the odorant receptors (ORs) in determining a given olfactory neuron's odor response profile is well-established, the more subtle mechanisms that may lead to different outcomes depending on environmental and behavioral context are less well-known. We are, therefore, interested in identifying novel genes expressed in olfactory neurons that modulate olfactory physiology. To do so, we have generated a library of >150 fly stocks that permit the tissue-specific overexpression of Drosophila miRNAs. MicroRNAs are single-stranded RNAs of approximately 22 nucleotides in length that play an important role in regulating gene expression by binding sequence-specifically to their target mRNAs and inducing their degradation. By crossing these UAS-miRNA lines to the Orco-GAL4 line, which is highly expressed in most olfactory neurons, we have used single sensillum electrophysiology to identify miRNAs that modulate the odor-evoked responses of OSNs in basiconic sensilla. Since the available methods for miRNA target prediction are prone to generating false positives, we are currently carrying out a smaller secondary screen using UAS-RNAi lines for predicted targets to identify the specific target mRNA(s) that are being affected in the positive hits from our primary screen.

Structural and functional differences in the antennae of worker honey bees of *Apis mellifera* and *Apis cerana*

Je won Jung[1], Kun woong Park[2], Hyung wook Kwon[3]

[1]Seoul national University, Republic of Korea, [2]Seoul national University, Republic of Korea, [3]Seoul National University, Republic of Korea

Olfactory discrimination, perception, and efficient orientation abilities to food resources play important roles for most insects in survival. The complexity of olfactory systems in a given species may depend on its feeding ecology and chemosensory abilities involved in inter and intra-specific recognition in their environment. The honey bee is a highly social insect and works together by a division of labor. To regulate the complex social interactions, honeybees have evolved an intricate system of special olfactory organs. To understand the differences of olfactory functional mechanisms in honeybee antenna, the structural and functional variations of worker bee antennae of two honey bee species, Apis mellifera and Apis cerana were compared using electron microscopic analysis, electrophysiological measurement, and proboscis extension reflexes (PER). Our present study showed that putative olfactory sensilla (placodea, trichodea, basiconica) were more significantly abundant on the A.cerana antenna than A.mellifera. Similarly, olfactory responses to various floral volatile compounds were higher in A.cerana than A.mellifera. In addition, PER responses were slightly different in two species. These findings may extend our understandings of the evolution of honey bee olfactory systems and behavioral traits to various ecological and biological signals between two closely related honey bee species.

Development and Reproduction

Neurohormonal control of desert locust (*Schistocerca gregaria*) reproductive physiology

Liesbeth Badisco[1], Pieter Van Wielendaele[2], Senne Dillen[3], Elisabeth Marchal[4], Jozef Vanden Broeck[5]

[1]KU Leuven, Belgium, [2]KU Leuven, Belgium, [3]KU Leuven, Belgium, [4]KU Leuven, Belgium, [5]KU Leuven, Belgium

The desert locust (Schistocerca gregaria) is a feared pest insect. Swarms consisting of billions of individuals can seriously damage the crop production in large areas of the world. The reproductive process of these animals may constitute an interesting target for pest control strategies and this fact stimulates fundamental research of locust reproduction. We recently produced an EST database derived from desert locust central nervous system (Badisco et al., 2011). Homology searches resulted in the identification of multiple transcripts encoding neuropeptides and lipophilic hormone biosynthesis enzymes that may be candidate key players in desert locust reproductive physiology. The availability of this novel transcript sequence information meant a great step forward in the desert locust reproduction research and allowed us to confirm the involvement of some neuropeptides in the process of vitellogenesis. Not only the production of mature gametes, but also the acquirement of the necessary nutritional energy is an essential part of the reproductive process. Some neurohormones may therefore indirectly control the locust's reproductive physiology by regulating feeding mechanisms and/or by acting as signal molecules that sense whether the required nutritional conditions are fulfilled to proceed to the reproductive processes. We recently studied the possible role in desert locust reproductive physiology of insulin-related peptide, neuroparsins, ovary maturating parsin/diuretic hormone, neuropeptide-like F and juvenile hormone biosynthesis enzymes.

The distribution and physiological effects of neuropeptides controlling reproductive tissues in the kissing bug, *Rhodnius prolixus*

Angela B Lange
University of Toronto Mississauga, Canada

Coordination of muscle contractions of the reproductive system in both male and female insects is critical for successful mating and the eventual production of viable eggs. This coordination involves a variety of neurons and their neuroactive chemicals. We have described these events in detail in the locust, Locusta migratoria, and shown that male and female reproductive tissues are under central neuronal control, with the neural substrate expressing an array of peptide and amine phenotypes. Central pattern generators (CPGs) are involved in oviposition, and the CPGs that control digging of the ovipositional hole, egg retention in the lateral oviducts and sperm release are synchronized. More recently, we have been examining the male and female reproductive systems of the medically-important bug, Rhodnius prolixus. Here again, these systems are under neuronal control, the neurons of which utilize a variety of neuropeptides to influence muscle contraction which again leads to successful mating and egg-laying. These peptides include proctolin, FGLamide/ASTs, FMRFamide-like peptides and myoinhibiting peptides (MIPs). The MIPs are believed to be the ancestral ligands for the Drosophila sex peptide receptor. The MIP precursor in R. prolixus encodes MIPs that have an unusual W(X7)Wamide motif. MIP-like immunoreactivity is found within neurons projecting to the female and male reproductive systems, and these peptides, along with others, influence muscle activity.

RNAi Technology reveals the roles of G-protein coupled receptors in moth reproductive behavior

Ada Rafaeli

Agricultural Research Organization, Volcani Center, Israel

Sex-pheromone production in the night flying female moth, Helicoverpa armigera is under neuroendocrine control due to Pheromone Biosynthesis-Activating Neuropeptide (PBAN) at which time calling females attract conspecific males. On reaching the females, males display their hair-pencil complexes that contain fatty acid derived "pheromonal" compounds, structurally similar to female sex-pheromones. The role of pheromone biosynthesis activating neuropeptide (PBAN) in the regulation of female sex-pheromone biosynthesis is well elucidated, but its role in males remained a mystery for over two decades, since its discovery from both male and female central nervous systems. Through RNAi-mediated gene-silencing of the G-protein coupled PBAN-receptor gene, we revealed the functionality of the PBAN-receptor and the key components that are up-regulated by PBAN in male hair-pencil complexes. After mating, females undergo drastic behavioral and physiological changes including the termination of sex-pheromone biosynthesis and an increase in oviposition behavior. Synthetic Drosophila melanogaster Sex-Peptide (DrmSP), which is responsible for terminating receptivity in female flies, can also terminate PBAN-stimulated sex-pheromone production; suppress calling behavior; and down-regulate the PBAN-receptor transcript levels. We identified a G-protein coupled receptor for Sex-Peptide in H. armigera (HeaSP-R) and a differential expression study revealed up-regulation of HeaSP-R transcript levels in female neural tissues and pheromone glands after mating. RNAi-mediated gene-silencing of the HeaSP-R expression by 50-60% prevented DrmSP-suppression of pheromone production and calling behavior. Moreover, mated, silenced females failed to increase their oviposition rates and their behavior did not differ from that of virgin females thereby implicating Sex-Peptide in the post-mating behavioral changes of this moth.

The potential for disrupting pupal diapause in *Heliothis/Helicoverpa* with diapause hormone

David Landis Denlinger[1], Qirui Zhang[2], Ronald J. Nachman[3]

[1]Ohio State University, U.S.A., [2]Ohio State University, U.S.A., [3]Southern Plains Agricultural Research Center, USDA/ARS, College Station, Texas, U.S.A.

Diapause hormone (DH), a 24-amino acid neuropeptide in the pyrokinin family, is best known for its action in inducing diapause in embryos of the silkmoth, Bombyx mori. But, interestingly, this same hormone can be used to break the pupal diapause in members of the Heliothis/Helicoverpa complex of pest species. Based on the structure of DH, we designed several agonists that are much more active than DH in breaking diapause. One of the agonists is 50x more potent than DH itself. One such agonist also prevents the entry into diapause when administered to larvae that have been environmentally programmed by short day length to enter diapause. We also used a unique antagonist development strategy of incorporating a dihydroimidazole ("Jones") trans-Proline mimetic motif into one of our DH agonists, thereby converting the agonist into a DH antagonist that blocks the termination of diapause. Thus, these new agents, which can be used to prevent, terminate, or block the termination of diapause, suggest possibilities for compromising the overwintering success of these pests insects.

Neuroparsin

Jan Adrianus Veenstra
The University of Bordeaux, France

The pars intercerebralis is the major center of neuroendocrine cells in the insect brain, which are grouped into the pars intermedia and the bilateral pars lateralis. Two cell types in the pars intermedia are stained using the classical neurosecretory stain paraldehyde fuchsin, one of these produce the insect insulin related peptides, and the other a hormone which is only known from arthropods, neuroparsin. Both cell types are almost ubiquitously present in insects, but the neuroparsin cells are absent from Drosophila melanogaster and other closely related Drosophila species. Given their strong affinity for paraldehyde fuchsin, the neuroparsin neuroendocrine cells were probably the first insect endocrine cells identified. Although we know very little about the function of this neurohormone, neuroparsin is a fascinating subject for conjecture and speculation as will be discussed.

Possible ETH role in regulation of juvenile hormone production in Bombyx

Dusan Zitnan[1], Ivana Daubnerova[2], Ladislav Roller[3], Klaus H. Hoffmann[4], Michael E. Adams[5]

[1]Institute of Zoology, SAV, Bratislava, Slovakia, [2]Institute of Zoology, SAV, Bratislava, Slovakia, [3]Institute of Zoology, SAV, Slovakia, [4]University of Bayreuth, Germany, [5]University of California, Riverside, U.S.A.

The silkworm Bombyx mori is a promising model species for functional analysis of neuroendocrine interactions controlling development and behavior. We used various molecular, biochemical and physiological approaches to study functions of ecdysis triggering hormones (ETH) from endocrine Inka cells and its ETH receptors (ETHR). Careful examination of ETHR expression using in situ hybridization and qRT-PCR revealed appearance of this receptor in multiple peptidergic and aminergic neurons of the CNS and in endocrine cells of the corpora allata (CA) prior to each ecdysis. Particularly strong ETHR expression was detected in endocrine cells of the CA several hours after each ecdysteroid peak in pharate larvae, pupae and adults. Increased levels of juvenile hormones (JH) following each ecdysis coincide with ETH release and suggest its possible direct action on the CA. Indeed, our preliminary experiments indicate that ETH elicits in vivo JH biosynthesis in pharate larvae. To further analyze the role of ETH-ETHR signaling in JH biosynthesis, we identified a CA-specific promoter for an enzyme aceto-acetyl CoA thiolase (AACT) using the baculovirus expression system. The AACT promoter with GCaMP and ETHR were subcloned into the piggyBac vector for production of transgenic animals. Resulting transgenic lines have been used for Calcium imaging and physiological experiments in vivo and in vitro. These experiments revealed unexpected neuroendocrine pathways between specific central neurons, Inka cells and corpora allata. Supported by Slovak grant agencies APVV (51-039105), VEGA (2-6090-26) and NIH (GM 67310).

Juvenile hormone titer and allatoregulating neuropeptides in wood-feeding cockroaches and primitive termites

Klaus H. Hoffmann[1], Franziska Wende[2]
[1]*University of Bayreuth, Germany,* [2]*University of Bayreuth, Germany*

Termites are eusocial insects with differentiated castes. They have two developmental systems, the linear pathway system or the dual-line system, and juvenile hormone (JH) plays a central role in caste regulation. Several studies have shown that JH titers are elevated in the course of soldier development. The synthesis of JH in the corpora allata of insects is regulated by allatostatins (AST) and allatotropins. Allatostatins of the FGLamide type (A-type) occur in many insect orders, but are known to inhibit JH biosynthesis only in cockroaches, crickets, and termites. The gene for the AST-A preprohormone has been identified in several cockroaches, but only in one termite species, Reticulitermes flavipes. We identified the gene for the prepro-AST peptides in the only genus of the basal termite family Mastotermitidae, the Darwin termite, Mastotermes darwiniensis. In addition, the expression of the gene in brain and gut of all developmental stages and castes is demonstrated. The gene codes for 14 individual peptides and its sequence is most similar to that of the xylophagous woodroach, Cryptocercus darwini. There is a strong negative correlation between expression of the AST-A gene in the brain and the haemolymph JH III-titer in different developmental stages of the fertile and the sterile line of M. darwiniensis (measured by HPLC-MS). Knock-down of the AST-A gene by RNA interference, however, did not affect the JH titer of female and male workers. Our results confirm wood-feeding cockroaches as direct ancestors of termites, as well as the FGLamides as true allatostatins in both insect groups.

RNAi of the allatotropin peptide precursors and allatotropin receptor highlighting their physiological role in insects: Focus on the red flour beetle, *Tribolium castaneum*

Roger Remi Huybrechts[1], Julie Tobback[2], Magdalena Bil[3], Kristel Vuerinckx[4]
[1]KU Leuven, Belgium, [2]KU Leuven, Belgium, [3]KU Leuven, Belgium, [4]KU Leuven, Belgium

In Tribolium we recently characterized the allatotropin GPCR receptor. RNAi knockdown started in the last larval stage of either receptor (Tc atr) or all three allatotropin-like peptide precursors. No developmental effects were observed. The limited number abnormal developmental phenotypes were not different from control gfp RNAi larvae. Compared to females we counted a significant lower number of emerging RNAi surviving receptor knockdown males. Being validated by an RNAi knockdown of all the allatotropin precursor isoforms simultaneously, this points to an important role of JH in developing and sexually maturing males of Tribolium. Importantly, these Tc atr RNAi males display a reduced reproductive capacity when mated with wild-type unmated females. Tc atr receptor transcript levels are surprisingly high in male accessory glands and predict a role for JH in male reproduction and accessory glands development in Tribolium males. Accordingly, the RAG glands have significant smaller sizes in Tc atr RNAi males compared to controls as is the case in JHAMT RNAi Tribolium males (Parthasarathy et al., 2009). Given the absence of this phenotypic effect on accessory glands in Trica-atl RNAi males, the receptor seems to be the limiting factor in stimulating JH synthesis/release by the male accessory glands. We can expect the high but incomplete knockdown of the allatotropin precursor mRNA's still

Epigenetic control of locust phase polymorphism

Liliane Schoofs[1], Arnold De Loof[2], Bart Boerjan[3]
[1]KU Leuven, Belgium, [2]KU Leuven, Belgium, [3]KU Leuven, Belgium

The morphological, physiological and behavioral differences between solitarious and gregarious desert locusts are so pronounced that one could easily mistake the two phases as belonging to different species.. A number of phase-specific features are hormonally controlled. Juvenile hormone promotes several solitarious features, the green cuticular colour being the most obvious one. The neuropeptide corazonin elicits the dark cuticular colour in the gregarious phase in addition to particular gregarious behavioral characteristics. However, endocrine factors may not be the primary cause in phase determination. Our observation that longevity gets imprinted very early in life and that it cannot be changed thereafter, made us consider the possibility that epigenetic control of gene expression might be the primary phase-determining mechanism. Imprinting is likely to involve DNA methylation and histone modification. Analysis of a Schistocerca EST database of nervous tissue identified the presence of several genes that may be involved in epigenetic regulation, including two DNA methyltransferases (Dnmts). Dnmt1 and Dnmt2 are phase-specifically expressed in certain tissues. In the metathoracic ganglion, important for serotonin mediated sensing of mechanical stimuli, the level of Dnmt1 and 2 expression is affected by crowding. Pilot methylome sequencing data indicate that DNA methylation in the desert locust goes up to 1.4% genomic cytosine methylation in the brain and metathoracic ganglion. This is the highest level observed in insects so far. So far, there is no evidence for a Dnmt3, a de novo DNA methyltransferase in locusts, which makes the desert locust a prime epigenetic model to study DNA methylation.

Functions of sNPF/CCAP autocrine metabolostat regulating feeding, behavior and reproduction in *Periplaneta americana*

Makio Takeda[1], Azam Mikani[2], Yoshiki Nagaba[3], Quishi Wang[4], Tufail Muhammad[5]

[1]Kobe University, Japan, [2]Kobe University, Japan, [3]Kobe University, Japan, [4]Kobe University, Japan, [5]Kobe University, Japan

Insects must adjust their physiological and behavioral conditions, according to the availability of food, allocating nutrients in their reservoir to most relevant function. Namely, starvation requires to shut down digestive activities, protein synthesis, mitosis and reproduction and to mobilize stored reservoir and stimulate autophagy and apoptosis. The refeeding reverses this process. The brain-midgut axis employs a variety of neurotransmitters, neuropeptides and growth factors in integrating physiological, metabolic, behavioral and reproductive functions in the American cockroach, Periplaneta americana, notably as we have shown (Sakai et al. 2004; Endocrinology 145,5671 and 2006 Peptides 27, 2157). CCAP from the brain and the midgut epithelium, interact and regulate digestive activities in the midgut.These brain-midgut interplay is affected by circadian oscillation, since the removal of pars intercerebralis upregulates the number of CCAP- and allatostatin-ir paraneurons, inducing hypertrophy only when the animal is placed in constant darkness (Matsui et al. 2009 Physiology and Behavior 96, 548 and unpublished data). sNPF production is enhanced under starvation both in the brain and midgut paraneurons. It is down-regulated by refeeding and CCAP injection, while CCAP is down regulated by sNPF but upregulated by refeeding.Since sNPF-ir and CCAP-ir were colocalized both in some neurons and paraneurons, this system functions as an autocrine system that regulates global physioology, behavior, metabolism and reproduction, since the injection of sNPF and starvation upregulate while the injection of CCAP and refeeding down-regulate locomotory activities. In Leptinotarsa dessimlineata, starvation suppresses the CA activity thus reproduction. Starvation often induces oosorption. Here the neuropeptide mechanism will be elucidated.

Behaviour-modifying peptides and peptidases of male accessory glands

R. Elwyn Isaac
University of Leeds, United Kingdom

Mating elicits various physiological and behavioural responses in post-mated female insects (e.g. male rejection and elevated ovulation rate). We have studied the effect of mating on wakeful activity and sleep in female drosophilids. In D. melanogaster, copulation promotes daytime wakefulness in the post-mated female; a change of behavior compatible with increased foraging and egg?laying activity. Extending this study to other Drosophila species suggests that the effects of mating on adult female wakefulness are species dependent. The altered behavior of D. melanogaster females is abolished if males lack sex peptide in the seminal fluid suggesting that SP, a male accessory gland (MAG) product, is the molecular switch. We have also studied behaviour -modifying peptides from the MAG of Aedes aegypti and showed that MAGs are an important source of head peptide (Aea-HP-1), first characterised by from mosquito heads and shown to inhibit host-seeking1. The peptide is made in the anterior portion of the gland and is transferred to the female during mating. A. aegypti often mate close to the host and therefore it is possible that male-derived Aea-HP-1 rapidly alters female host-seeking behaviour to reduce potentially lethal encounters with hosts soon after insemination. Both D. melanogaster SP and A. aegypti Aea-HP-1 are structurally designed to withstand attack by the plethora of peptidases present in insect seminal fluid. The cyclic structure of SP and the presence of blocked N- and C-termini in Aea-HP-1, confer resistance to seminal fluid peptidases. 1Matsumoto S. et al. Insect Biochem. 1989;19:277-83.

The significance of PISCF allatostatins in beetles

Neil Audsley[1], Hans Peter Vandersmissen[2], Robert Weaver[3], June Matthews[4], Jozef Vanden Broeck[5]
[1]Fera, United Kingdom, [2]KU Leuven, Belgium, [3]Fera, United Kingdom, [4]Fera, United Kingdom, [5]KU Leuven, Belgium

The insect PISCF/allatostatins (ASTs) are pleiotropic peptides that are involved in the regulation of juvenile hormone biosynthesis, are myoinhibitory on the gut and the heart, and suppress feeding in various insects, but their roles in beetles are poorly understood. To provide further insight into the significance of PISCF/ASTs in beetles, the PISCF/AST receptor from Tribolium castaneum has been characterised and its tissue distribution determined, as well as the biological activity of the T. castaneum PISCF/AST (Trica-AS). The Trica-AS receptor shows high sequence homology to other insect PISCF/AST receptors, which are related to the mammalian somatostatin/opioid receptors, a family of G-protein coupled receptors. The Trica-AS receptor was activated in a dose-dependent manner by both Trica-AS and Manduca sexta-AS, but somatostatin was inactive. Receptor and peptide transcript levels in tissues, determined by qRT-PCR, were highest in the Brain/retrocerebral complex, ventral nerve cord and/or the gut. The distribution of peptide was also shown to be widespread using an ELISA to Trica-AS, with highest levels in Malpighian tubules and , brain/ retrocerebral complex. The widespread distribution of both Trica-AS and its receptor suggest this peptide may have multiple roles in beetles. However, Trica-AS had no effect on the spontaneous contractions of the gut or ovaries of T. castaneum but this peptide did stimulate the release of enzymes from the anterior midgut of another beetle, Tenebrio molitor.

Control of molt and metamorphosis in *Sesamia nonagrioides* (Lepidoptera, Noctuidae)

Valeriya Zabelina[1], Matilde Eizaguirre[2], Frantisek Sehnal[3], Meritxell Perez-Hedo[4]

[1]Biology Centre, Czech Academy of Sciences, Czech Republic, [2]UdI IRTA, Spain, [3]Biology Centre, Czech Academy of Sciences, Czech Republic, [4]UdI IRTA, Spain

Sesamia caterpillars develop in 5-6 larval instars and under short day conditions enter diapause as fully grown 6th instar larvae which then undergo up to 10 stationary larval molts. Diapause is maintained by moderate juvenile hormone (JH) titer and is readily terminated under long day conditions. In contrast to other Lepidoptera, brain is not essential driver of molt and development. On the contrary, brain removal in Sesamia caterpillars causes an increase of ecdysteroid titer. Decerebration of larvae in the 3rd or a later instar may first induce one or more larval molt(s) and/or elicit pupation followed by the imaginal molt. The incidence of induced larval molts is enhanced by the brain implants that elevate JH titer. Precocious pupation, including termination of larval diapause, occurs also in the decapitated larvae but the resulting headless pupae do not molt unless supplied with exogenous JH or ecdysteroids. Then they secrete a new cuticle combining pupal and imaginal features. Decapitated larvae develop beyond the pupal stage when implanted with the suboesophageal ganglia (SG) or with the corpora cardiaca-corpora allata complexes, whereas larvae deprived specifically of SG and retaining all other organs, molt to pupae and then their development stops. The results show that SG plays important role in the control of pupal-adult molt and that delicate hormonal interactions are crucial for proper progress of metamorphosis in Sesamia.

Induction of diapause and seasonal morphs in butterflies and other insects

Soren Nylin
Stockholm University, Sweden

The 'choice' whether to enter diapause or to develop directly has profound effects on the life histories of insects, and may thus have cascading consequences such as seasonal morphs and other less obvious forms of seasonal plasticity. Here, I briefly review recent advances regarding knowledge of the control of diapause and seasonal morphs at the genetic and physiological levels. I then use examples from my own research (primarily on butterflies) as a starting point for outlining some areas of research where we still have a limited understanding: The photoperiodic response is often modified by e.g. temperature and hostplants, but to what extent are these responses adaptive? Are growth rate differences between pathways causes or consequences? What is the role of parental effects and sex linkage on the photoperiodic control? Are seasonal morphs always adaptive?

Possible involvement of cryptochrome and opsins in photoperiodic regulation of nymphal development in the cricket *Modicogryllus siamensis*

Kenji Tomioka[1], Saori Tamaki[2], Saki Takemoto[3]
[1]Okayama University, Japan, [2]Okayama University, Japan, [3]Okayama University, Japan

The cricket Modicogryllus siamensis shows photoperiod-dependent changes in its nymphal development: Nymphs become adult within 50 days after hatching undergoing seven molts in long day conditions (LD), while in short day conditions (SD) they take much longer periods (~180 days) for nymphal development, showing an increased number of molting. Since removal of the compound eyes resulted in altered photoperiodic responses, they are a likely photoreceptor involved in the photoperiodic response. In the present study, using RNAi technology, we have examined the role of opsins expressed in the compound eye and cryptochromes in the photoperiodic response. With molecular cloning, we obtained cDNAs of three opsins, i.e. opsin-long wave (opLW), opsin-UV (opUV) and opsin-Blue (opBL), and two cryptochromes, i.e. drosophila-type cryptochrome (cry1) and mammalian-type cryptochrome (cry2). The opsin genes expressed in specific regions of the compound eye with a gene specific manner. RNAi of the opsin genes resulted in a partial disruption in the LD responses; up to 20% of the treated crickets showed a SD-like response with a prolonged nymphal period and an increased number of molting. RNAi of cry1 and cry2 also disrupted LD response in about 50% of the treated crickets. But with both opsin and cry RNAi no distinct alterations were observed in SD responses. These results suggest that the opsins and crys may play different roles in the photoperiodic response at least to LD in the cricket and they may work together for controlling proper photoperiodic responses.

Photoperiodic response under control of circadian clock genes in the bean bug *Riptortus pedestris*

Shin G. Goto[1], Tomoko Ikeno[2], Kimika Ishikawa[3], Hideharu Numata[4]

[1]Osaka City University, Japan, [2]Osaka City University, Japan, [3]Osaka City University, Japan, [4]Kyoto University, Japan

Most organisms have evolved a circadian clock in order to anticipate daily environmental changes and many of these organisms are also capable of sophisticated measurement of daylength (photoperiodism). It has been generally accepted that the same elements are involved in both circadian (daily) and seasonal (annual) rhythms because both rely upon daily light-dark cycles. However, there remains little conclusive evidence of such molecular machinery in insects. We have approached this issue by using RNA interference (RNAi) in the bean bug Riptortus pedestris. First we verified the circadian clock genes period (per) and mammalian-type cryptochrome (cry-m) function as negative regulators, and cycle (cyc) and Clock (Clk) function as positive regulators, in the circadian clock governing the cuticle deposition rhythm of this species. RNAi directed against negative and positive regulators produced distinct cuticle layers. Simultaneously, per and cry-m RNAi caused the insect to avert diapause under a diapause-inducing photoperiod whereas cyc and Clk RNAi induced diapause under a diapause-averting photoperiod. Thus, RNAi directed against negative and positive regulators had opposite effects not only in the circadian clock but also in the photoperiodic response. This study revealed that the circadian clock operated by per, cry-m, cyc and Clock governs seasonal timing as well as the daily rhythms.

Transcriptomic basis of seasonal photoperiodism regulation in the pea aphid

Gael Le Trionnaire[1], Stephanie Jaubert-Possamai[2], Nathalie Leterme-Prunier[3], Sylvie Hudaverdian[4], Sylvie Tanguy[5], Fabrice Legeai[6], Jean-Christophe Simon[7]

[1]INRA, France, [2]INRA, France, [3]INRA, France, [4]INRA, France, [5]INRA, France, [6]INRA, France, [7]INRA, France

Aphids are one of the major pests of crops. They reproduce by parthenogenesis during spring and summer and by sexual reproduction in autumn. This switch is driven by a seasonal photoperiodism. At fall, viviparous parthenogenetic females detect photoperiod shortening and initiate the production of sexual individuals (males and oviparous females) in their offspring that will mate: fertilized sexual females will lay cold-resistant eggs that overcome harsh winter conditions. In order to describe the molecular bases involved in the regulation of seasonal photoperiodism in aphids, we developed a transcriptomic approach. We build a 7000 cDNAs microarray to study the transcriptome of heads of aphids ? where the detection and transduction of the photoperiodic signal might occur ? reared under short or long photoperiod. We could identify more than 500 different transcripts as significantly regulated in response to photoperiod shortening. Their functional classification allowed us to confirm the involvement of the neuro-endocrine system in the transduction of the signal but also to discover unexpected features such as a possible modification of cuticle structure. Indeed, the down-regulation of transcripts involved in the conjugation of dopamine and ß-alanin to form NBAD-sclerotin suggested a putative desclerotization of the cuticle under short photoperiod. Transcripts coding major enzymes involved in dopamine biosynthesis were also found be down-regulated in those conditions suggesting that dopamine levels might be decreasing under short photoperiod. A similar observation was made for transcripts involved in Insulin signaling and degradation pathways, also suggesting a possible inhibition of Insulin signalization in response to photoperiod shortening.

Arylalkylamine N-acetyltrasferase is the neuroendocrine interface regulating photoperiodism for pupal diapause of the giant silk moth, *Antheraea pernyi*

Makio Takeda[1], Ahmed Mahmoud[2], Jadwiga Bembenek[3], Taketo Tsugehara[4], Qiushi Wang[5]

[1]Kobe University, Japan, [2]Kobe University, Japan, [3]Kobe University, Japan, [4]Kobe University, Japan, [5]Kobe University, Japan

Photoperiodism is a complex system regulated both by the circadian system and endocrine switch. Antheraea pernyi has a pupal diapause instituted when larvae developed under short-days , that can be terminated by the exposure of pupae to long-days for at least 10 cycles or incubated after a cold exposure of several months. The critical endocrine regulation for this developmental determination is whether the peptide hormone, PTTH is released or not from two pairs of neurons at the dorsolateral protocerebrum. The PTTH neurons juxtapose to the circadian neurons that express circadian proteins, Period and Doubletime. these neurons also express arylalkylamine N-acetyltransferase, NAT and NAT activity and the downstream product, melatonin show circadian fluctuation under LD cycles. NAT is activated by the exposure to long-days more than ten cycles and during chilling. We cloned nat gene and analyzed the upstream regulatory region. The upstream reagion contains several E-boxes where clock transcription modulator complex Cycle/Clock can bind.Namely nat is a ccg, clock-controlled gene. We then injected double strand RNA to knock down NAT and exposed diapause pupae to long-day condition. RNA-i worked beautifully to show photoperiodism was impaired under long day condition and no moth emerged after the injection under short-day. This proved that NAT is a critical interface of all photoperiodic clock components, circadian output pathway, photoperiodic counter and endocrine switch, as nat gene activation by circadian transcription modulator, circadian regulation of enzymatic activity of NAT, circadian regulation of melatonin and endocrine switch by melatonin binding at melatonin receptor expressed on

Endocrine mechanisms underlying loss of seasonal reproductive polyphenism in the pea aphid

Asano Ishikawa[1], Hiroki Gotoh[2], Kota Ogawa[3], Toru Miura[4]

[1]National Institute of Genetics, Japan, [2]Hokkaido University, Japan, [3]Hokkaido University, Japan, [4]Hokkaido University, Japan

Most aphids alter the reproductive modes from parthenogenesis to sexual reproduction in response to short photoperiod (reproductive polyphenism). Although the reproductive polyphenism is thought to have acquired in early step of aphid evolution, many populations secondarily lost the sexual phase and are insensitive to photoperiodic changes. To understand molecular mechanisms of reproductive polyphenism and its secondary loss, we investigated the endocrine regulations responsible for reproductive polyphenism among several populations of the pea aphid, Acyrthosiphon pisum. First, we examined roles of juvenile hormone (JH), which was considered a likely candidate for regulating the reproductive-mode switch, and JH-related genes in aphid reproductive polyphenism. JH measurements and applications revealed that low JH titer under short day induced the sexual-morph production. Furthermore, under this condition, higher expressions of genes encoding JH-degrading enzyme were suggested to cause the low JH titer. Next, to investigate molecular underpinnings causing the evolutionary loss of sexual phase, we examined JH titer and JH-related gene expressions under long/short day in asexual populations that are though to have lost reproductive polyphenism. Neither JH titer nor JH-related genes show photoperiodic responses. Thus, it is suggested that the modification of JH degradation pathway in response to photoperiodic changes caused the loss of reproductive polyphenism in aphids.

Pupal color polyphenism in the swallowtail butterflies, *Papilio xuthus* and *P. machaon*

Akira Yamanaka
Yamaguchi University, Japan

Many butterflies show pupal color polyphenism. Environmental properties of pupation sites, such as background color, texture and curvature, affect the development of pupal coloration in many species, whereas environmental factors, such as experienced during the larval or pharate pupal stages, such as photoperiod and temperature, also affect pupal coloration in some Papilionid, Lycaenid and Pierid species. In the swallowtail butterfly, pupae of Papilio xuthus exhibit color polyphenism, such as pupae of green or brown types in non-diapause pupae, and pupae of diapause-green, orange or brownish-orange types in diapause pupae by photoperiodic condition during larval stages. Pupal coloration of this species is controlled by hormones that have been named pupal-cuticle-melanizing hormone (PCMH) and orange-pupa-inducing factor (OPIF). The former is involved the development of brown pupae in non-diapause pupae, while the latter is involved in the development of orange pupae in diapause pupae. On the other hand, P. machaon also exhibits pupal color diphenism, such as pupae of green-yellow types or brown-white types. But, there is little information about the development of pupal coloration in P. machaon. The present talk will deal with the effects of environmental factors on pupal coloration and the properties of hormonal factors affecting pupal coloration in two swallowtail butterflies P. xuthus and P. machaon.

Inheritance of photoperiodic control of pupal diapause in the cotton bollworm, *Helicoverpa armigera* (Hubner)

Fangsen Xue[1], Chao Chen[2]
[1]*Jiangxi Agricultural Unversity, China,* [2]*Jiangxi Agricultural Unversity, China*

The cotton bollworm, Helicoverpa armigera (Hubner) enters a facultative pupal diapause in response to short-day conditions. Due to geographic variation in photoperiodic response, moths from a northern population from Langfang (39.53° N, 116.68° E) enter diapause in response to short daylengths even at the higher temperatures (D strain) whilst moths from southern population from Ledong (18° 47′ N, 108° 89′ E) exhibit almost no diapause under the same conditions (N strain). In the present study, crosses between the two strains are utilized to evaluate the inheritance of diapause under different photoperiods at temperatures 20, 22 and 25°C. The moths in both reciprocal crosses and backcrosses to D strain show a clear long-day response, similar to that of the D strain. The incidences of diapause for all F1 hybrids are intermediate between those of their parents. However, the male parent plays more important role in the determination of diapause. The N strain also shows a short-day photoperiodic response at the lower temperature of 20°C. Results from all crosses under photocycles LD 12 : 12 h or LD 13 : 11 h at 22 °C show that the capacity for diapause is transmitted genetically in the manner of incomplete dominance. Diapause duration in hybrid pupae is also influenced by their inheritance from both parents. These results reveal that both photoperiodic control of diapause induction and the duration of diapause are under the control of polygene.

Effect of photoperiod on flight propensity and induction of adult diapause in the water strider *Limnoporus genitalis* (Hemiptera: Gerridae).

Rinshiro Masuda[1], Shiro Nakao[2]
[1]*Kyoto Prefectural University, Japan,* [2]*Kyoto Prefectural University, Japan*

The water strider, Limnoporus genitalis (Miyamoto), which inhabits the Sakhalin and the Kurile Islands in Russia and the Hokkaido Island in Japan, is known as a monomorphic macropter. The effect of photoperiod during nymphal stages on relative wing length (fore wing length, hind wing length / head width), wing area, wing loading, flight muscle development and take-off, and the induction of female adult diapause in L. genitalis was examined by conducting rearing trials under various photoperiodic conditions (from 10L to 17L / 24h) at 20°C. There were no differences in relative wing length or wing area of individuals reared under long-day conditions (17L-7D) compared to those reared under short-day conditions (15L-9D and 10L-14D). However, wing loading was significantly larger in females reared under long-day conditions compared to those reared under short-day conditions. The percentage of adults possessing fully developed flight muscles and taking off was significantly higher in individuals reared under short-day conditions compared to those reared under long-day conditions. Short-day conditions comprising less than 15 h light induced adult diapause in females. These results and a similar study concerning L. esakii (Miyamoto) suggested that photoperiod strongly influences the seasonality of dispersal in the water strider genus Limnoporus in Japan. Although increasing flight propensity and induction of female adult diapause under short-day conditions was common in both species, the percentage of individuals possessing fully developed flight muscles and percentage of individuals which flew more readily was higher in L. genitalis compared to the endangered species L. esakii.

Surviving winter: Diapause syndrome in the southern green stink bug *Nezara viridula* in the laboratory, in the field, and under climate change conditions

Dmitry L. Musolin
Saint Petersburg State University and Saint Petersburg State Forest Technical University, Russia

The southern green stink bug, Nezara viridula (L.) (Heteroptera: Pentatomidae), has long attracted attention not only as a serious pest of numerous agricultural crops but also as a species expanding its range in many parts of the world. The paper focuses on reproductive (i.e., adult) winter diapause, which is the pivotal element of the species' seasonal cycle. Results from numerous field experiments and observations, as well as laboratory eco-physiological investigations conducted during the few last decades, are analysed and interpreted. Experimental findings are used to describe the dynamics of physiological changes during overwintering. Reproductive diapause in N. viridula is controlled in both sexes by photoperiodic conditions. Induction of diapause is associated with a reversible change of body colour from green or yellow to russet (= brown). The proper timing of adult emergence and diapause induction as well as the size of adults are vitally important for successful overwintering. Nezara viridula has been shown to respond strongly to the current climate change by shifting its northern range limit, particularly in central Japan. Analysis of historical climate data suggests that, the environmental conditions during the last few decades have become more favourable for overwintering survival of N. viridula in many locations in central Japan. This has likely promoted the northward spread of the species. The relationships between reproductive diapause, reversible body colour changes, overwintering success and the recent range expansion are analysed. Perspectives of the range dynamics of the species are discussed in light of further predicted climate change.

A lunar rhythm derived from photoperiodic induction of diapause? Experimental dissection of lunar rhythms in the marine midge *Clunio marinus*

Tobias S Kaiser[1], David G Heckel[2]
[1]*Max F Perutz Laboratories, Austria,* [2]*Max Planck Institute for Chemical Ecology, Germany*

In the marine midge Clunio marinus (Chironomidae, Diptera) adult emergence is timed to the tides by means of circadian and circalunar clocks. Experiments suggest that during secondary colonization of marine habitats, the circalunar clock may have derived from photoperiodic diapause: The lunar rhythm is based on a short developmental arrest of the larvae at the same stage at which photoperiodic diapause takes place. The circalunar clock is entrained via a period of nocturnal moonlight-sensitivity under the control of a circadian clock. As tidal regimes differ along the coast, C. marinus comprises many locally adapted timing races which differ in various aspects of their lunar and diurnal rhythms. Crossing experiments revealed genetic control of diurnal and lunar emergence times. Linkage mapping and quantitative trait locus (QTL) analysis identified two loci each controlling the two traits. The QTL comprise several circadian clock genes and light receptor genes. Lunar and diurnal emergence times are not inherited independently and their QTL partially overlap. This suggests that one gene may influence both traits and there may be a molecular interaction of circadian and circalunar clocks. Alternatively, evolution may have shaped genetic architecture to stabilize adaptive combinations of lunar and diurnal emergence time through genetic linkage. Currently, the C. marinus genome is being assembled and the parental strains of the crosses are screened for strain-specific polymorphisms. This may eventually reveal the first known molecular components of the circalunar clock, which may also shed new light on photoperiodic diapause induction.

New developmental gene functions identified by a genome-wide RNAi screen in the four beetle Tribolium

Martin Klingler[1], Gregor Bucher[2], The iBeetle Consortium[3]

[1]Erlangen University, Germany, Germany, [2]University of Gottingen, Institute of Zoology, Germany, [3]Several Universities, Germany

Much what we know about the genetics of insect biology is based on work in Drosophila melanogaster. However, some features of the higher Dipterans are derived, i.e. not representative for insects in general, or hard to study due to technical reasons. In addition, not all gene functions have been identified due to redundancies by lineage specific gene duplications or gene loss. A number of alternative insect model systems are being established which complement and validate Drosophila data. Tribolium castaneum stands out due to well established transgenic techniques, a strong and systemic RNAi response and a sequenced genome. In order to overcome current limitations in insect science, we perform a genomewide RNAi screen (see also http://ibeetle.uni-goettingen.de/). In this functional genomics screen we want to (1) identify missing components of well studied processes, including embryonic development. (2) we want to open new fields of insect research to functional analysis, and (3) we aim at developing Tribolium into a complementary screening platform to identify genes that will then be studied in detail in other systems. Up to date, we have injected over 4000 dsRNAs, each into both, pupae and 6th instar larvae, to identify genes with functions in embryonic development and metamorphosis. Some of the new gene functions identified in this process will be presented at the meeting. We are committed to make the functional data from this screen available to the community, and also the our library of dsRNA templates will be provided for future such screens in Tribolium.

Exploring mechanisms of embryonic patterning in *Gryllus bimaculatus*, a hemimetablous insect model system

Taro Mito[1], Taro Nakamura[2], Tetsuya Bando[3], Takahito Watanabe[4], Sumihare Noji[5]

[1]The University of Tokushima, Japan, [2]The University of Tokushima, Japan, [3]The University of Tokushima, Japan, [4]The University of Tokushima, Japan, [5]The University of Tokushima, Japan

Mechanisms of embryonic patterning have been extensively studied in Drosophila melanogaster, a holometabolous insect. However, the mode of embryogenesis in Drosophila is highly derived and recent studies on other insects have revealed that there exist new developmental paradigms. The cricket Gryllus bimaculatus is an emerging model species for studying developmental mechanisms in hemimetabolous insects. In the past decade, RNAi-based gene function analyses greatly promoted our understanding of developmental gene networks in G. bimaculatus. Germline transformation and gene-knockout techniques have been more recently established in this species. Furthermore, we are conducting whole-genome sequencing of G. bimaculatus. Our previous studies revealed conserved and divergent aspects of the anterior-posteiror (AP) patterning system in the cricket, in comparison with other insects. Based on our recent progress, we will discuss evolution of AP patterning mechanisms in insects.

Role of Wnt and BMP signaling pathways in the regional specification of early blastoderm in the cricket *Gryllus bimaculatus*

Taro Nakamura[1], Taro Mito[2], Tetsuya Bando[3], Sumihare Noji[4]

[1]University of Tokushima, Japan, [2]University of Tokushima, Japan, [3]University of Tokushima, Japan, [4]University of Tokushima, Japan

The mode of insect embryogenesis varies among species reflecting adaptations to different life history strategies. In Drosophila, a holometabolous insect, the Bicoid (Bcd) gradient acts as a morphogen to establish the anterior-posterior pattern. However, although Bcd is essential to anterior patterning in Drosophila, no ortholog has been isolated in any insect apart from the higher dipterans. Recent studies with these insects has been revealed that Wnt/Caudal and BMP signaling has a crucial role for AP and DV axes patterning, but how cell movement is coordinated with cell specification by inputs of these signaling pathways during the early blastoderm formation are poorly understood. To understand how the Wnt and BMP signaling pathways contribute to establishment of the DV and AP axes in Gryllus, we analyze the molecular function using parental-RNAi technique with GFP-expressing cricket. We find that the canonical Wnt signaling regulates posteriorly localization of caudal expression to specify regional identity of the posterior growth zone and that may control migration direction of embryonic cells to form a germ anlage. Furthermore, our preliminary results show that prior to AP-axis specification by Wnt signaling, BMP signaling may be involved not only in specification of DV axis but also in that of AP axis through the control of posterior aggregation of the embryonic cells during early blastoderm formation. Our data suggest that the regional specification of early blastoderm is specified by BMP signaling through the regulation of cell movement earlier than by Wnt signaling.

The function of protein phosphatase 6 in the programmed cell death in the insect midgut

Chuan-Xu Wang[1], Peng-Cheng Liu[2], Jin-Xing Wang[3], Xiao-Fan Zhao[4]

[1]Shandong University, China, [2]Shandong University, China, [3]Shandong University, China, [4]Shandong University, China

Programmed cell death (PCD) plays an important role in insect midgut remodeling during metamorphosis. Insect midgut PCD is triggered by the steroid hormone 20-hydroxyecdysone (20E) and it is mediated by a series of genes. However, the mechanism by which 20E triggers midgut PCD is not fully understood. Here, we report a protein phosphatase 6 (PP6) from Helicoverpa armigera playing roles in midgut PCD. PP6 is expressed in the midgut during larval growth and it is significantly increased during metamorphosis. The increase is proven to be regulated by 20E. The juvenile hormone analog methoprene has no effect on PP6 expression. RNA interference analysis suggests that 20E upregulates the PP6 transcript levels through the ecdysone receptor EcRB1. PP6 knockdown by larval feeding or PP6 dsRNA injection results in the repression of the midgut PCD during the metamorphic stage. The mechanism is demonstrated to be through the suppression of genes such as Br, E74a, E75b, HR3, E93, rpr, and caspase, which are involved in 20E signaling pathway or midgut PCD. These findings suggest that PP6 is involved in the 20E signal transduction pathway and participates in the PCD in midgut. This work was supported by the grants from the National Natural Science Foundation of China (No. 30970404) and National Basic Research Program of China (973 Program, 2012CB114101).

The evolution of dorsoventral patterning in insects

Siegfried Roth
University of Cologne, Germany

The gene regulatory network (GRN) underpinning dorsal-ventral (DV) patterning and gastrulation of the Drosophila embryo is among the most thoroughly understood GRNs, making it an ideal system for comparative studies seeking to understand the evolution of development. With the emergence of widely applicable techniques for testing gene function, species with sequenced genomes, and multiple tractable species with diverse developmental modes, a phylogenetically broad and molecularly deep understanding of the evolution of DV axis formation in insects is feasible. I will review recent progress made in this field with particular focus on the evolution of EGF, Toll and BMP signaling.

Evolution of insect thoracic morphology: Emerging views

Aleksandar Popadic
Wayne State University, U.S.A.

The first insight into the development of insect thorax and the generation of individual thoracic segmental identities were provided by now classic studies of hox genes in Drosophila some thirty years ago. These studies established the paradigm where Antennapedia (Antp) provides the default thoracic identity observed in the mesothorax (T2), whereas Sex combs reduced (Scr) and Ultrabithorax (Ubx) generate the distinct morphologies of prothorax (T1) and metathorax (T3), respectively. Because Drosophila undergoes a derived, holometabolous mode of development, we analyzed the function of these three genes in a hemimetabolous species, Oncopeltus fasciatus. The embryonic function of Antp is localized to T2 legs only, with the main effect observed in the mid-distal leg segments. However, the Antp-RNAi has no effect on the identity of the T2 segment as a whole. In a similar fashion, while Scr regulates the formation of combs on T1 legs, it does not control the overall identity of the T1 segment. This is different from the function of Ubx, which establishes the key features of the T3 segment, such as its distinct pigmentation and the repression of thoracic spiracles. These results indicate the presence of significant differences between the holo- and hemimetabolous species in regard to the development of distinct thoracic morphologies. The emerging insight from Oncopeltus also highlights the fact that the genetic mechanisms that generate the default thoracic identity (that of the T2) are yet to be determined.

Morphological diversity of wing serial homologues in the mealworm beetle, *Tenebrio molitor*

Takahiro Ohde[1], Toshinobu Yaginuma[2], Teruyuki Niimi[3]
[1]Nagoya University, Japan, [2]Nagoya University, Japan, [3]Nagoya University, Japan

Of various flying animals on the earth, insects have evolved a unique flight organ. Evolutionary origin of insect wing is a long-standing question. In modern pterygota, wing appears only on meso- and metathorax. However, as insect body is composed of mutually homologous segments, the organ that is serially homologous with wing should exist in non-winged segments. Identification of such structure would provide a clue to understand origin and evolution of insect wing. In this study, we aimed to identify the wing serial homologues in the mealworm beetle, Tenebrio molitor. To identify putative wing serial homologues in non-winged segments, we examined the process of segment transformation from a non-winged segment toward a winged segment by comparing weakly and strongly affected Hox RNAi phenotypes of Tenebrio. Through such observation, we identified prothoracic hypomeron and pupal abdominal gin-traps as candidates of wing serial homologues. To obtain further support, we analyzed homologues of Drosophila key wing field regulators, vestigial (vg) and scalloped (sd). Surprisingly, in situ expression analysis and RNAi functional analysis of Tenebrio vg and sd homologues revealed that both genes play crucial roles in hypomeron and gin-trap formation, as in wing formation. These data suggests that prothoracic hypomeron and abdominal gin-traps are serially homologous with wing. From this study, insect wing serial homologues could be redefined as the source of diverged adaptive structures such as hypomeron, gin-trap and wing.

Dachsous/Fat signaling via Hippo/Salvador/Warts pathway regulates cell proliferation and pattern formation during leg regeneration in the cricket

Tetsuya Bando[1], Yoshimasa Hamada[2], Taro Nakamura[3], Taro Mito[4], Hideyo Ohuchi[5], Sumihare Noji[6]

[1]The University of Tokushima, Japan, [2]The University of Tokushima, Japan, [3]The University of Tokushima, Japan, [4]The University of Tokushima, Japan, [5]The University of Tokushima, Japan, [6]The University of Tokushima, Japan

Regeneration depends on the recognition of tissue loss and the subsequent restoration of the relevant structure. The two-spotted cricket Gryllus bimaculatus is hemimetabolous insect and restores lost part of leg in epimorphic manner during several molts subsequent to amputation. Pattern formation of cricket regeneration legs along proximodistal axis is established by Hedgehog, Wingless, Decapentaplegic and Egfr signlaing, however, numerous questions remain, including how they detect positional disparity along the proximodistal axis, how they accurately restore the leg to its normal size, and what factors govern blastemal cell proliferation in the correct proportions. To address these questions, we have studied the molecular biological basis of leg regeneration in the Gryllus bimaculatus revealed by RNAi. We focused on genes involved in the Dachsous/Fat signaling pathway, which have been recently implicated in cell proliferation, planar cell polarity and proximodistal patterning. We found that Dachsous/Fat signaling regulates cell proliferation in blastema and in host stump and regulates positional information along proximodistal axis during leg regeneration. Since many molecules involved in cricket leg regeneration are conserved in vertebrates, our findings will provide cues to understand the longstanding questions on regeneration in metazoa.

Freeze tolerance in drosophilid flies: A comparison of two species, the fruit fly and the malt fly.

Vladimir Kostal
Biology Centre, Academy of Sciences of the Czech Republic, Czech Republic

Insect cold tolerance represents a complex of impressive strategies. A whole array of biochemical and physiological adjustments counteract damaging effects of subzero temperatures, e.g. accumulation of low molecular weight cryoprotectants, synthesis of antifreeze proteins, remodeling of cellular membranes, and accumulation of heat shock proteins. Some insect species display the highest known levels of cold tolerance among all animals. For instance, larvae of the malt fly, Chymomyza costata (Drosophilidae) survive after submersion in liquid nitrogen (-196?C) in a fully hydrated state. We found that the principles underlying freeze tolerance in malt fly larvae are transferable, at least partially, onto a chill susceptible larvae of fruit fly, Drosophila melanogaster. Given the fact that the evolutionary adaptation for freeze tolerance is generally considered as highly complex and uneasy to mimic in laboratory, our recent results are encouraging and may open a new direction of research on long-term cryogenic storage of biological material. So far, cryogenic protocols have been developed for embryos of several insect species, including D. melanogaster. Despite indisputable progress, methods for crypreservation of insect embryos were not widely implemented into practice. The long term cryogenic storage of complex animal tissues or whole organisms still remains a great challenge. In these respect, detailed analysis of C. costata model appears as greatly promising.

Insect cold storage technology: Design and practical applications

Roger Allen Leopold
USDA-ARS Fargo, ND, U.S.A.

Most insects used in research, pest control or other beneficial applications have relatively short shelf-lives. Unless a particular species has the inherent capacity to enter some type of dormancy, colony maintenance is usually by continuous culture. Continuously rearing insects in small numbers as for research can be expensive and time consuming. Rearing insects in large numbers as for pest control or pollination of beneficial crops is subject to numerous production problems. Development of insect storage technology can help alleviate many difficulties associated with nonstop insect rearing. With this motivation, our research group conducts studies with the purpose of devising short- and long term storage methodology for a variety of insects. For short-term storage, the most cold-tolerant growth stage is stored at a non-freezing temperature which promotes developmental quiescence. Recent work with solitary bees shows that a fluctuating thermal regime allows greater storage time and more quality insects than a constant temperature regime. Methods using liquid nitrogen cryopreservation have been developed for long-term storage of 6 dipteran species and one lepidopteran. Transfer of insect cryopreservation technology has resulted in preservation of 10 genetically-specific strains of screwworm embryos representing 25,000 individuals. Current projects involving formation of embryo cryobanks for insect production facilities have progressed to where protocols for several species have been upgraded to process >2000 embryos for each run with a potential of cryopreserving >10,000 embryos per 8 hr period.

Transcriptome sequencing reveals molecular components of diapause preparation in the Asian tiger mosquito, *Aedes albopictus*

Peter Armbruster[1], Monica Poelchau[2], Christine Elsik[3], Julie Reynolds[4], David Denlinger[5]

[1]Georgetown University, U.S.A., [2]Georgetown University, U.S.A., [3]Georgetown University, U.S.A., [4]Ohio State University, U.S.A., [5]Ohio State University, U.S.A.

The Asian tiger mosquito, Aedes albopictus, is currently among the most invasive mosquitoes in the world. This species is also of particular public health concern due to its ability to efficiently transmit Dengue fever, Chikungunya, West Nile and a variety of other arthropod-borne viruses. The photoperiodic diapause of Ae. albopictus is a critical ecological adaptation that has facilitated its rapid spread throughout temperate habitats. We have utilized studies of life-history variation to identify adaptive changes to the diapause response during invasion and range expansion and reproductive trade-offs associated with diapause. Additionally, next generation sequencing approaches have been used to identify the underlying molecular physiology of diapause in Ae. albopictus. Our results show rapid evolution of diapause timing during the range expansion of Ae. albopictus in North America. Next-generation sequencing approaches and quantitative RT-PCR have identified transcriptional differences in lipid metabolism genes contributing to diapause-associated reproductive tradeoffs. Next-generation sequencing has also been used to identify transcriptional elements of the diapause response related to morphogenesis, additional metabolic pathways and stress response.

A role for insulin signaling as a regulator of mosquito diapause

David L. Denlinger[1], Cheolho Sim[2]
[1]Ohio State University, U.S.A., [2]Baylor University, U.S.A.

Females of the northern house mosquito, Culex pipiens, overwinter in a reproductive diapause, characterized by an arrest in development of the ovarian follicles, fat accumulation, enhanced stress resistance, suppressed metabolic rate, and a behavioral switch from blood feeding to sugar feeding. This developmental arrest has been well documented to be linked to a shut-down in juvenile hormone (JH) production, and consistent with this view is the observation that the ovarian follicles can be prompted to resume development with an application of JH. Our recent experiments compliment the earlier link with JH by investigating the role of insulin signaling in the pathway leading to diapause. Using RNAi to block the insulin receptor in nondiapause programmed females, we generate the diapause phenotype (arrested ovarian development). Application of JH will rescue this arrest, suggesting that insulin signaling is upstream of the JH pathway. RNAi directed against the transcription factor FOXO, a gene downstream of insulin, prevents diapause-programmed females from accumulating the fat reserves normally associated with diapause. Using a FOXO antibody and CHiP sequencing we have identified a number of candidate genes that are downstream of FOXO and likely contribute to generating the diapause phenotype. Experiments with additional species suggest that the insulin/FOXO pathway may be a common element in the regulation of diapause.

Embryonic diapause of the silkworm Bombyx mori occurs immediately after the completion of mesoderm segregation and the enlargement of the two extremities of the embryo. This diapause is induced by the action of a neuropeptide hormone, diapause hormone that consists of 24 amino acid residues with amidation at the C-terminus. Diapause hormone is biosynthesized in the subesophageal ganglion of the mother, released from it through the corpora cardiacum-corpora allatum into the hemolymph and targets the developing ovaries during the mid-pupal stage. The diapause hormone signal is received by diapause hormone receptor on oolemma, transduced to the inside of oocyte and finally connected to expression of the diapause initiating gene, pnd (pigmented and non-diapausing egg), which leads to stop the embryonic cell division at the G2 phase after completion of mesoderm segregation to enter diapause. As long as these eggs are incubated at 25oC continuously, the diapause state is maintained for about one year. To break completely the diapause, exposure to 5oC for more than 60 days is required. How is the release of diapause hormone into the hemolymph controlled? How is the diapause hormone signal connected to expression of pnd? How is the diapause broken by continuous 5oC-exposure? Our recent efforts to understand these molecular mechanisms will be discussed.

Stress tolerance in the Antarctic midge, *Belgica antarctica*

Richard Earl Lee Jr[1], David L. Denlinger[2]
[1]*Miami University, U.S.A.,* [2]*Ohio State University, U.S.A.*

In polar regions tolerance of low moisture conditions is likely as important for terrestrial organisms as cold hardiness. The midge Belgica antarctica is the southernmost free-living insect. Overwintering larvae must endure months of continuous subzero temperatures and encasement within an icy substrate without access to free water. Our recent studies examined physiological and molecular mechanisms of stress tolerance in this polyextremophilic species. Heat shock proteins (Hsps) protect organisms from injury due to temperature, anoxia, desiccation, and chemical stresses. Typically these proteins are only expressed in response to environmental stress, however summer larvae express these proteins continuously--suggesting they play a critical role in maintaining the integrity of key enzymes or other proteins in the cold. Larvae also have the capacity to rapidly cold-harden (RCH) within 1 h while frozen at -5°C, the lowest temperature known for RCH induction. Water relations are intimately linked to larval cold tolerance. Larvae are remarkably susceptible to dehydration but survive losing > 70% of their osmotically active water. Furthermore, dehydration confers increased tolerance of freezing; dehydrated larvae readily survive 3 d at -10ºC, whereas hydrated larvae cannot. Osmotic challenge caused by either dehydration or immersion in seawater elevates hemolymph osmolality and increases the synthesis of sugars and polyols. Metabolomic and proteomic studies identified other common responses to desiccation and freezing. We acknowledge of the many contributions of our students and colleagues to this research and support from the National Science Foundation (ANT-0837559 and ANT-0837613).

Drying out to survive the winter: Using RNA-seq to identify genes involved in overwintering in the Antarctic midge, *Belgica antarctica*

Nicholas Mario Teets[1], Justn T. Peyton[2], David L. Denlinger[3]
[1]Ohio State University, U.S.A., [2]Ohio State University, U.S.A., [3]Ohio State University, U.S.A.

The Antarctic midge, Belgica antarctica, is the world's southernmost insect and t he only insect endemic to the continent. Larvae are extremely tolerant of a number of environmental stresses, most notably desiccation; larvae can tolerate up to 70% water loss under ecologically relevant conditions. This ability to dehydrate is important for winter survival, as desiccated larvae are more cold-tolerant than their fully-hydrated counterparts. Furthermore, larvae are capable of using cryoprotective dehydration, an overwintering strategy in which larvae remain unfrozen by gradually losing water until the body fluid vapor pressure equals that of surrounding ice. In this study, we explored the molecular mechanisms of both desiccation (93% RH at 4°C for 5d) and cryoprotective dehydration (gradual chilling to -3°C at equilibrium with the vapor pressure of ice) using RNA-Seq. Using paired-end Illumina sequencing, we assembled roughly ~14,000 transcripts and measured their expression in response to desiccation and cryoprotective dehydration. Both treatments had a dramatic impact on the transcriptome, as ~25% of all transcripts were differentially expressed relative to fully-hydrated controls in each treatment. The gene expression profiles were largely similar for both treatments, including differential regulation of a number of genes related to the heat shock response, cell death pathways, detoxification, and central metabolism. However, despite these overall similarities, clustering analysis indicated that the desiccation and cryoprotective dehydration groups were transcriptionally distinct. Our results are the first large-scale transcriptomics study for a polar insect and begin to unravel the molecular mechanisms of stress tolerance in perhaps the world's most extreme insect.

Global analysis of hemolymph and brain metabolites during initiation and maintenance of pupal diapause in the cotton bollworm, *Helicoverpa armigera*

Yu-Xuan Ly[1], Wei-Hua Xu[2]
[1]*Sun Yat-Sen University, China,* [2]*Sun Yat-Sen University, China*

Yu-Xuan Lv, Wei-Hua Xu* State Key Laboratory of Biocontrol and School of Life Sciences, Sun Yat-Sen University,Guangzhou 510275, China. *Email:xuweihua@mail.sysu.edu.cn Abstract Environment is not always suited to organism's development. Hence, insects have evolved a strategy called diapause, for resistant the harsh conditions. The cotton bollworm, Helicoverpa armigera, is an agricultural pest, and can resist rigorous conditions through entering diapause at pupal stage. Using gas chromatography-mass spectrometry (GC-MS) based metabolomic techniques, we compared the metabolites in the brain and hemolymph between nondiapause- and diapause-type pupal. Totally, 55 metabolites in the hemolymph and 52 metabolites in the brain were identified. There are 21 and 12 metabolites altered in diapause-type pupal hemolymph and brain. Moreover, several metabolites also changed during diapause initiation. Metabolites accumulated in diapause-type pupal hemolymph including β-alanine, leucine, proline, valine and phosphoric acid, etc. In addition, methionine and tyrosine were dropped in the hemolymph during diapause. However, the major of metabolites decreased in diapause pupal brain except aspartate. Finally, a cluster of amino acids (glutamate, leucine, phenylalanine, proline and valine) changed after the diapause termination. We speculated that these altered metabolites regulated energy resource pools and enhanced stress resistance for organism. Meanwhile, they may be involved in several developmental signaling to influence diapause process.

Temperature effects on the prolonged egg diapause of a katydid, Paratlanticus ussuriensis

Kyeong-Yeoll Lee[1], jae-Kyoung Shim[2], Hae-Son Bang[3]

[1]Kyungpook National University, Republic of Korea, [2]Kyungpook National University, Republic of Korea, [3]RDA, Republic of Korea

Diapause of Paratlanticus ussuriensis eggs can be prolonged to more than one year depending on environmental conditions. Eggs can enter an initial facultative diapause in the early embryonic stage and then enter a final obligatory diapause in the fully developed embryo stage. Initial diapause is temperature-dependent; it is initiated at 20?C and breakdown at 30?C. To determine the effects of temperature on the mechanism of initial diapause of P. ussuriensis eggs, we compared weight and DNA and RNA contents of eggs that were incubated at either 20?C or 30?C for 60 days after oviposition. Both weight and total DNA of eggs were constant when incubated at 20?C but gradually increased when incubated at 30?C. Total RNA content increased over 15 days then remained at a high level when eggs were incubated at 30?C whereas RNA content was at a constant low level when eggs were incubated at 20?C. In addition, we cloned 5 heat shock protein (hsp) genes, shsp, hsp70a, hsp70b, hsp70c and hsp90, from P. ussuriensis and determined those mRNA levels in relation to diapause. Unlike other hsp genes, hsp70c was uniquely peaked at 30?C, but not at 20?C, at the time of the initiation of initial diapause. Our results suggest that high temperature interrupts the initial diapause and induces embryonic development in the eggs. Upregulation of hsp70c may be associated with inhibitory mechanism of initial diapause entrance at high temperatures.

Development and Reproduction

Juvenile Hormone Synthesis Undressed

Crisalejandra Rivera-Perez[1], Marcela Nouzova[2], Mark E. Clifron[3], Fernando Gabriel Noriega[4]

[1]Florida International University, U.S.A., [2]Florida International University, U.S.A., [3]Florida International University, U.S.A., [4]Florida International University Miami, FL, U.S.A.

Juvenile hormone (JH) is a key modulator of metamorphosis and ovarian maturation in mosquitoes. Adult female Aedes aegypti mosquitoes show developmental and nutritionally regulated changes of JH synthesis. To understand the molecular bases of these dynamic changes we combined transcriptional studies of the enzymes of the JH pathway with functional analysis of JH synthesis and the flux of its precursors. The lipophilic character of JH, its low concentration, fragility and the tendency to bind nonspecifically to everything had made difficult its quantification. A sensitive and robust new method was developed to quantify JH and its precursor pools in biological samples. The assay is based on the derivatization of JH with fluorescent tags, with subsequent analysis by reverse phase HPLC and a fluorescent detector. Linear responses were obtained over the range of 10-20 to 1000 fmols. FA and JH III levels were reproducibly quantified from corpora allata, hemolymph and whole body of female adult mosquito (in addition, JH III and JH III bisepoxide were detected in whole body of adult Drosophila melanogaster). Nutritional deficient mosquito females had reduced transcript levels for the genes encoding JH biosynthetic enzymes and reduced JH synthesis. Our studies suggest that JH synthesis is controlled by the rate of flux of isoprenoids, which is the outcome of a complex interplay of changes in precursor pools, enzyme levels and external regulators such as nutrients and brain factors. Enzyme levels might need to surpass a minimum threshold to achieve a net flux of precursors through the biosynthetic pathway.

Molecular characterization of moltinism mutants of the silkworm, *Bombyx mori*

Takaaki Daimon[1], Tetsuro Shinoda[2]
[1]*National Institute of Agrobiological Sciences, Japan,* [2]*National Institute of Agrobiological Sciences, Japan*

Silkworms typically have five larval instars, but the number of larval instar varies from three to seven in "moltinism" strains. For example, precocious metamorphosis is observed in mod (dimolting, 11-27.4), rt (recessive trimolter, 7-9.0) and M3 (Moltinism, 6-24.1) strains, while extra larval molting is observed in M5 (Moltinism, 6-24.1) strains. To uncover the molecular basis of moltinism in insects, we have performed positional cloning of these loci. Here, we report the identification and characterization of the gene responsible for the mod locus. All the mod larvae underwent precocious metamorphosis at the end of 3rd or 4th instar. Methoprene application to mod larvae during the 3rd or 4th instar was able to prevent precocious metamorphosis, and most of the treated larvae successfully developed into pupae after 5th instar, suggesting that JH reception and signaling pathway are not impaired in mod larvae. We performed fine mapping of mod and were able to narrow the responsible region within ~400 kb. Notably, we found a silkworm P450 gene CYP15C1 within this region, an ortholog of cockroach CYP15A1 that catalyzes epoxidation of metyl farnesoate to juvenile hormone in cockroach corpora allata. In mod mutant, CYP15C1 gene had a premature stop codon, and the JH titer in the hemolymph at the 3rd instar was below the detectable level. These defects could be rescued when wt allele was expressed using the GAL4/UAS transgenic system, demonstrating that CYP15C1 is responsible for mod and plays an essential role in JH biosynthesis.

The juvenile hormone-methoprene-tolerant complex regulates maturation of the adult optic lobe and female receptivity in *Drosophila*

Lynn M. Riddiford[1], Julide Bilen[2]
[1]*Howard Hughes Medical Institute, U.S.A.,* [2]*Howard Hughes Medical Institute, U.S.A.*

Juvenile hormone (JH) has two roles: 1) prevents the switching actions of ecdysone that are necessary for metamorphosis; 2) regulates reproductive maturation in the adult. In Drosophila melanogaster, the JH receptor is encoded by two genes: germ cells expressed (gce) and Methoprene-tolerant, a duplicate of gce. Both the gce2.5K and the Met27 null mutants form viable adults with Met27 showing delayed egg maturation and reduced fecundity, but the double mutant dies at head eversion to the pupa, similarly to wild type pupae lacking the corpora allata (CAX). Both CAX and Met27 prepupae show precocious development of the optic lobe (OL) that is rescued by JH only in the CAX prepupae. In contrast, the gce2.5K null mutant shows no precocious development of the OL. Expression of Met RNAi in selected neurons shows that JH is acting in the photoreceptors to prevent the premature differentiation caused by the pupariation peak of ecdysteroids. CAX adult females are delayed in becoming receptive to courting males; exogenous JH prevents this delay. The loss of Met causes a similar delay, but the loss of Gce has no effect on this behavior. Expression of Met RNAi in brain neurons known to be involved in female receptivity also delays its onset, suggesting that JH acts via Met to promote the maturation of these neurons. Thus, although Met and Gce are redundant in maintaining viability to adulthood and preventing premature fat body development (Li et al, 2009), each also has its own functions in modulating development of specific tissues.

Met-mediated JH signaling in adult mosquitoes

Jinsong Zhu[1], Meng Li[2]
[1]*Virginia Tech, U.S.A.*, [2]*Virginia Tech, U.S.A.*

Egg maturation in mosquitoes is governed mainly by two insect hormones: the sesquiterpenoid juvenile hormone III (JH-III), and the steroid hormone 20-hydroxyecdysone (20E). Deprivation of JH in newly emerged adult female mosquitoes will halt egg maturation. Interestingly, topical application of a JH analog shortly after blood feeding inhibits the normal 20E response and also impairs egg maturation. The molecular mechanisms underlying JH action remain largely unknown. We have demonstrated that the mosquito Methoprene-tolerant protein (AaMet) and a p160/SRC coactivator of the ecdysteroid receptor complex, AaFISC, are crucial for the post-eclosion activation of some JH target genes in newly emerged adult mosquitoes. AaMet and AaFISC, two bHLH-PAS transcription factors, form a heterodimer in the presence of JH. Transcriptional activation of the JH target genes results from the recruitment of the heterodimer to JH response elements in the regulatory regions of target genes. Using structure modeling and functional analysis, our preliminary studies indicate that the PAS-B domain of AaMet is essential for high affinity binding of JH. Structurally driven mutagenesis has generated several AaMet mutants that exhibit different transactivation activities in response to JH and it's analogs, ranging from abolished activation, selective response to pyriproxyfen but not JH-III and methoprene, to constitutive activation even in the absence of JH. These preliminary results indicate that our structural- functional approach is a promising tool to uncover the structural basis for Met to act as a JH-regulated transcription factor.

MET is required for maximal action of 20-hydroxyecdysone in inducing gene expression and tissue remodeling during Bombyx metamorphosis

Enen Guo[1], Sheng Li[2]
[1]*Shanghai Institutes for Biological Sciences, China,* [2]*Shanghai Institutes for Biological Sciences, China*

Little is known about how the juvenile hormone (JH) receptor, bHLH-PAS transcription factor MET, is involved in 20-hydroxyecdysone (20E) action. Here we report that two MET proteins found in the silkworm, Bombyx mori, not only mediate JH action to induce Kr-h1 expression, but also are involved in 20E signal transduction. Met is 20E responsive and peaks during molting and pupation, when the 20E titer is high. As found with results from RNAi knockdown of EcR-USP, the 20E nuclear receptor genes, RNAi knockdown of Met at the early wandering stage disrupts the 20E-triggered transcriptional cascade, preventing tissue remodeling and causing lethality during larval-pupal transition. MET recruits general transcriptional co-activator CBP/p300 to EcR-USP for transactivation via the 20E response element. Moreover, MET binds E-box in promoter regions of the 20E-response genes and directly induces their expression. Conclusively, the 20E induction of MET is required for the maximal action of 20E in inducing gene expression and tissue remodeling during Bombyx metamorphosis. We propose that MET plays a role mediating JH-20E crosstalk.

Broad complex in hemimetabolan metamorphosis: The case of cockroaches

Jia-Hsin Huang[1], Jesus Lozano[2], Xavier Belles[3]

[1]National Taiwan University, Taiwan, [2]Institute of Evolutionary Biology (CSIC-UPF), Spain, [3]Institute of Evolutionary Biology (CSIC-UPF), Spain

Broad-Complex (BR-C) is a gene of the ecdysteroid signaling pathway that encodes a family of C2H2 zinc-finger transcription factors. In Drosophila melanogaster, BR-C expresses four protein isoforms, and null mutants in which none of the four isoforms is expressed remain in a prolonged larval state and never molt to pupae. In Manduca sexta, Bombyx mori and Tribolium castaneum, BR-C is expressed in the final larval stage, and this expression is essential for pupal metamorphosis. These are holometabolous models, and the only study in hemimetabolous species reports that BR-C regulate gradual morphogenesis in Oncopeltus fasciatus. We have studied the role of BR-C in the post-embryonic development of Blattella germanica, a phylogenetically basal hemimetabolous species whose BR-C gene encodes six protein isoforms. In this species, BR-C in significantly expressed in juvenile nymphal instars, whereas the expression decreases in the last one. This expression pattern parallels that of juvenile hormone (JH) production, and JH treatment up-regulates BR-C expression in the last instar nymph. These data suggest that in B. germanica BR-C belongs to the ecdysteroid cascade but is also JH-dependent. Antepenultimate instar nymphs treated with dsRNA targeting all BR-C isoforms molt to last instar, and then to adults with reduced wings. These results indicate that in cockroaches BR-C isoforms regulate progressive development of wing buds and finally wing formation. This seems the only apparent morphogenetic role of BR-C in our basal hemimetabolous model, and is also conserved in distal holometabolous species, which suggests that this is an ancestral function of BR-C.

Signaling through the JH receptor Met and the repressor of metamorphosis Kr-h1 is common to insects

Marek Jindra[1], Jean-Philippe Charles[2], Thomas Iwema[3], V. Chandana Epa[4], Keiko Takaki[5], Barbora Konopova[6], Vlastimil Smykal[7], Jan Rynes[8]

[1]Biology Center ASCR, Czech Republic, [2]Universite de Bourgogne, France, [3]Universite de La Reunion, France, [4]CSIRO, Australia, [5]Hirosaki University, Japan, [6]Biology Center ASCR, Czech Republic, [7]Biology Center ASCR, Czech Republic, [8]Biology Center ASCR, Czech Republic

We show that the bHLH-PAS Methoprene-tolerant (Met) proteins from the beetle (Tribolium), the firebrat (Thermobia) and both Drosophila paralogs (Met and Gce) bind juvenile hormone (JH III). JH mimics pyriproxyfen and methoprene are Tribolium Met agonists. Specific mutations within the PAS-B fold of Met reduce JH binding. Met mutants incapable of hormone binding fail to interact with a partner protein Taiman. The same mutation does not affect a Met-Met complex, and makes it resistant against JH-dependent dissociation. Therefore, Met requires JH bound to its PAS-B in order to leave the homodimer and to bind Taiman. Met thus establishes a new class of intracellular hormone receptors. The capacity of Met to sense JH occurs in the ametabolous Thermobia and therefore predates metamorphosis. We further show that JH signals through a 'common-core' pathway in both holometabolous and hemimetabolous insects, the latter represented by the true bug, Pyrrhocoris. In either insect type, JH requires Met to block metamorphosis during prefinal larval stages by maintaining high expression of Kruppel-homolog 1 (Kr-h1). In final-instar Pyrrhocoris larvae, a natural drop of JH titer and consequently of Kr-h1 expression permits adult morphogenesis. Depletion of either Met or Kr-h1 in the penultimate instar triggers precocious adult development instead of the final larval instar. Conversely, exogenous JH given to final-instar Pyrrhocoris larvae re-induces Kr-h1 and causes an extra larval instar, and this effect requires Met (see Figure). The anti-metamorphic function of JH, Met and its target Kr-h1 is therefore universal to insects with diverse types of metamorphosis.

Prothoracicotropic hormone signaling in prothoracic glands of the silkworm, *Bombyx mori*

Shi-Hong Gu
National Museum of Natural Science, Taiwan

Prothoracicotropic hormone (PTTH) is the stimulator of ecdysteroidogenesis by prothoracic gland in larval insects. We investigated signal transduction events initiated by PTTH in prothoracic glands of the silkworm, Bombyx mori. Our studies showed that PTTH inhibited the phosphorylation of adenosine 5'-monophosphate-activated protein kinase (AMPK) both in vitro and in vivo. PTTH-inhibited AMPK phosphorylation appears to be reversed by treatment with LY294002, indicating involvement of phosphatidylinositol 3-kinase (PI3K) signaling. The chemical activator of AMPK (5-aminoimidazole-4-carboxamide-1-β-d-ribofuranoside, AICAR) increased both basal and PTTH-inhibited AMPK phosphorylation. Treatment with AICAR also inhibited PTTH-stimulated ecdysteroidogenesis by prothoracic glands. The mechanism underlying inhibition of PTTH-stimulated ecdysteroidogenesis by AICAR was further investigated by determining the phosphorylation of 4E-Binding protein (4E-BP) and p70 ribosomal protein S6 kinase (S6K), two known downstream signals of the target of rapamycin (TOR). It was found that upon treatment with AICAR, a decrease in PTTH-stimulated phosphorylation of 4E-BP and S6K was detected. In addition, treatment with AICAR did not affect PTTH-stimulated extracellular signal-regulated kinase (ERK) phosphorylation, indicating that AMPK phosphorylation is not related to ERK signaling. From these results, it is assumed that the inhibition in AMPK phosphorylation, which lies in an upstream signaling of PTTH-stimulated TOR signaling, may play a role in PTTH stimulation of ecdysteroidogenesis.

Identification and characterization of Noppera-bo, a novel Halloween-class ecdysteroidogenic enzyme

Sora Enya[1], Yuko Shimada-Niwa[2], Yoshinori Fujimoto[3], Tetsuro Shinoda[4], Ryusuke Niwa[5]

[1]University of Tsukuba, Japan, [2]University of Tsukuba, Japan, [3]Tokyo Institute of Technology, Japan, [4]National Institute of Agrobiological Sciences, Japan, [5]University of Tsukuba, Japan

In insects, the precise timing of molting and metamorphosis is strictly guided by ecdysteroids, which are synthesized from the dietary cholesterol via several specific catalytic steps. In the last decade, a number of ecdysteroidogenic enzymes, including the Rieske oxygenase, the short chain dehydrogenase/reductase and several cytochrome P450 monooxygenases, have been identified and characterized at the molecular level. Besides these identified enzymes, here we report a novel ecdysteroidogenic enzyme, designated Noppera-bo, which belongs to the glutathione S-transferase family. noppera-bo was identified as a gene predominantly expressed in the PG of the fruit fly Drosophila melanogaster using the microarray analysis. We have isolated several noppera-bo mutant alleles and showed that complete loss of noppera-bo function mutants show embryonic lethality and naked cuticle structure. These phenotypes are typical for the Halloween-class mutants showing embryonic ecdysteroid deficiency. Importantly, the embryonic phenotypes are rescued by a topical application of 20-hydroxyecdysone, indicating that noppera-bo mutant phenotypes are primarily caused by ecdysteroid loss. A phylogenic analysis suggests that the noppera-bo family is well conserved in Diptera and Lepidoptera. We also show that an ortholog of noppera-bo from the silkworm Bombyx mori is also predominantly expressed in the PG. In addition, the overexpression of B. mori noppera-bo rescues the phenotypes of loss-of noppera-bo function animals. These results suggest that the novel Halloween-class enzyme Noppera-bo plays an essential role in ecdysteroid biosynthesis across different insect orders. Further molecular function of Noppera-bo in ecdysteroid biosynthesis will be discussed.

Ecdysone receptors: Structure and biology

Ronald Johnston Hill[1], Donya Tohidi-Esfahani[2], Lloyd D. Graham[3], Matthew Pollard[4], Linda Howell[5], Ross Terrence Fernley[6], Julian Grusovin[7], George Lovrecz[8], Louis Lu[9], Tram Phan[10], Pat Pilling[11], Bin Ren[12], Victor Streltsov[13], Thomas S. Peat[14], David .A Winkler[15], Michael C. Lawrence[16]

[1]CSIRO, Australia, [2]CSIRO, Australia, [3]CSIRO, Australia, [4]CSIRO, Australia, [5]CSIRO, Australia, [6]CSIRO, Australia, [7]CSIRO, Australia, [8]CSIRO, Australia, [9]CSIRO, Australia, [10]CSIRO, Australia, [11]CSIRO, Australia, [12]CSIRO, Australia, [13]CSIRO, Australia, [14]CSIRO, Australia, [15]CSIRO, Australia, [16]Walter and Eliza Hall Institute and University of Melbourne, Australia

The first biochemical evidence for an ecdysone receptor was the competition between N-ethylmaleimide and 20-hydroxyecdysone (20E) observed by Michael Ashburner in support of a central role for this protein in the Ashburner model. Verification of the model led somewhat adventitiously to the cloning of the gene encoding the EcR subunit of the ecdysone receptor which we now know to be a heterodimer of EcR and the protein USP. In ecdysone receptor structures holding 20E or the phytoecdysteroid ponasterone A, the ecdysteroid is completely enclosed within the EcR ligand binding domain with it's A and B rings in the vicinity of the β-sheet and its alkyl chain in the vicinity of helix 12.The ecdysteroid binding pocket (LBP) is accompanied by a smaller enclosed cavity termed the ancillary pocket. Three regions of the LBP will be distinguished based on degree of complimentarily with the ligand and residue conservation. We are beginning to understand the biological properties of ecdysone receptors in terms of atomic structure including the preference for different ecdysteroid hormones in particular insects. A hypothesis to explain the selectivity of the dibenzoylhydrazine insecticides for the Lepidoptera will be discussed and Ashburner's classical experiments interpreted in terms of LBP structure. The phytophagous Green Vegetable Bug, Nezara viridula, exhibits an increased preference for makisterone A over 20E. The N. viridula EcR is highly unusual in presenting a Leu substitution for an Ile in region 2 of its LBP within van der Waals distance of the additional methyl group on C24 of makisterone A.

Two adjacent cis-regulatory elements are required for the ecdysone response of ecdysone receptor (EcR) gene in Lepidoptera

Haruhiko Fujiwara[1], Hiroyuki Shirai[2], Manabu Kamimura[3], Junichi Yamaguchi[4]

[1]University of Tokyo, Japan, [2]University of Tokyo, Japan, [3]National Institute of Agricultural Sciences, Japan, [4]University of Tokyo, Japan

Nuclear receptors, EcR, E75, and HR3, are key regulators in the ecdysone-inducible gene activation cascade in insects. The transcription of these genes is induced by ecdysteroid (20-hydroxyecdysone, 20E) differently, although the detailed mechanisms underlying their responses to 20E are largely unknown. We here identify the ecdysone response elements (EcREs) for BmEcR-B1, BmE75-A, and BHR3-B isoforms from Bombyx mori using an ecdysteroid-responsive cultured cell aff3. Starting from a long upstream region of each gene that showed a 20E response, we used luciferase reporter assays to identify the respective EcREs in aff3. The EcRE of BmEcR-B1 at ? 2800, which showed ~30-fold induction by 20E, comprises two adjacent elements separated by 5bp, E1 (15 bp) and E2 (21 bp), both of which are required for the 20E response. A gel shift assay showed that E1 binds to the EcR/USP heterodimer and that E2 putatively binds with some E-box (CACGTG) binding factor such as bHLH protein. The unique E1+E2-type EcRE is also functional in other two lepidopteran cell lines, and highly conserved among promoter regions of EcR-B1 in seven lepidopteran species. By contrast, both a 20 bp EcRE (~50-fold induction) for BmE75-A and 18 bp EcRE (~1500-fold induction) for BHR3-B, comprise the E1-type EcR/USP binding element, which is also highly conserved among Lepidoptera. The combination of the E2 element or other cis-regulatory element in promoter regions may explain the different 20E responses of each class of nuclear receptor genes.

Local functions of the secreted insulin-antagonist Imp-L2 in *Drosophila*

Hugo Stocker[1], Ladan Sarraf-Zadeh[2], Rudiger Bader[3], Stefan Christen[4], Paola Cognigni[5], Katja Koehler[6], Irene Miguel-Aliaga[7], Michael Pankratz[8], Ernst Hafen[9]

[1]ETH Zurich, Switzerland, [2]ETH Zurich, Switzerland, [3]University of Bonn, Germany, [4]ETH Zurich, Switzerland, [5]University of Cambridge, United Kingdom, [6]ETH Zurich, Switzerland, [7]University of Cambridge, United Kingdom, [8]University of Bonn, Germany, [9]ETH Zurich, Switzerland

The secreted peptide Imaginal morphogenesis protein-Late 2 (Imp-L2) acts as a growth inhibitor in Drosophila by systemically controlling the activity of the most potent growth-inducing insulin, the Drosophila insulin-like peptide 2 (Dilp-2). Imp-L2 is expressed in distinct populations of cells in various tissues such as the brain, the ring gland, the gut and the fat body, raising the question whether it also acts locally at these sites. We demonstrate that locally increasing Imp-L2 expression in the brain using a specific Imp-L2-Gal4 driver results in a developmental delay. Conversely, development is slightly accelerated in Imp-L2 mutants. These effects on developmental timing are due to alterations of ecdysone production by the prothoracic gland (PG), which are not caused by elevated Imp-L2 levels in the hemolymph but most likely result from increased Imp-L2 production in neurons targeting the PG. Our results indicate that Imp-L2 expressing neurons act as sensors of the nutritional state in Drosophila larvae and coordinate dietary information and ecdysone production to assure proper developmental timing. Furthermore, we show that Dilp-2 is secreted at specific sites in the brain-ring gland complex, where Imp-L2 expressing cells take it up. We demonstrate that the Dilp-2 uptake is dependent on Imp-L2, and that it specifically increases insulin signaling activity in Imp-L2 expressing cells. Thus, in addition to their endocrine functions, Dilp-2 and Imp-L2 act together to locally promote insulin signaling in distinct neurons of the Drosophila brain.

The insulin signaling pathway is required for the death of crochet forming cells during pupal metamorphosis

Kiyoshi Hiruma[1], Mari Akitomo[2], Yasuhiro Sugime[3], Yu Kaneko[4]
[1]Hirosaki University, Japan, [2]Hirosaki University, Japan, [3]Hirosaki University, Japan, [4]Hirosaki University, Japan

Crochets are a larval specific tissue that are used to hold food plants in lepidopterans and its forming cells degenerate during the last instar stadium. The competence of the cells to form crochets in Bombyx mori declined gradually in the first two days after the last larval ecdysis, and they died 24 hr later. Both juvenile hormone and ecdysone had little effect on the change in competence, but starvation after the final larval ecdysis prevented the decline of the competence. Therefore, nutrition was responsible for its decline, and sucrose among the nutrients was the most important. Interestingly, insulin application to the larvae fed on normal diet rescued the competence, but injection of wortmannin, an inhibitor of the insulin signaling pathway, neutralized the insulin action. The expression of the insulin receptor gene in the crochet cells of normally developing larvae gradually declined, which was paralleled to the decline of the competence, but its expression increased by ~10 fold in the starved larvae. These results indicate that unlike the established role of the insulin signaling pathway, this pathway is stimulated by the lack of nutrition and is necessary for maintaining the competence of the cells to produce crochets, which is due to part of the stimulation of insulin receptor expression by starvation. Supported by the JSPS.

Developmental hourglass and the chicken and egg causality dilemma

Pavel Tomancak
MPI-CBG, Germany

There is a remarkable similarity in the appearance of groups of animal species during periods of their embryonic development. This classic observation has long been viewed as an emphatic realization of the principle of common descent. Despite the importance of embryonic conservation as a unifying concept, models seeking to predict and explain different patterns of conservation have remained in contention. The hourglass model that predicts excessive constraint during the mid-embryonic phylotypic period has recently received increasing support from genomics data. We will discuss several lines of evidence, from the molecular data, through developmental networks to life-history strategies, that indicate that early animal embryos are not highly conserved. Bringing this evidence together, we argue that the nature of early development often reflects adaptation to diverse ecological niches. Finally, we synthesize old and new ideas to propose a model that accounts for the evolutionary process by which embryos have come to be conserved.

The evolution of novel and diverse mechanisms of arthropod germ cell specification

Ben S. Ewen-Campen[1], Seth Donoughe[2], Tamsin Jones[3], Evelyn E. Schwager[4], John R. Srouji[5], Victor Zeng[6], Donald Nat Clarke[7], Cassandra Gabrielle Extavour[8]

[1]Harvard University, U.S.A., [2]Harvard University, U.S.A., [3]Harvard University, U.S.A., [4]Harvard University, U.S.A., [5]Harvard University, U.S.A., [6]Harvard University, U.S.A., [7]Harvard University, U.S.A., [8]Harvard University, U.S.A.

Germ cells in many Holometabolous insects, including Drosophila, are specified by maternal deposition of localised "germ plasm" that contains molecular determinants of germ cell fate. However, basally branching Hemimetabola and other arthropods are classically described as lacking germ plasm. Using molecular markers and functional genetics, we test the hypothesis that a zygotic, inductive signaling mechanism may have been used ancestrally for germ line specification within insects and arthropods. In two hemimetabolous insects and a spider, we find that transcripts and proteins of highly conserved "germ plasm genes", including piwi, vasa and nanos, are ubiquitously, rather than asymmetrically, localized during oogenesis and early embryogenesis. In all cases, molecular identification of primordial germ cells matches classical literature descriptions of the time and place of germ cell specification in late embryogenesis. Functional studies show that maternally provided vasa and piwi are not required for germ cell formation. We discuss emerging functional evidence for an exclusively zygotic requirement for these genes, and the role of conserved cell signaling mechanisms, in germ cell specification. We also explore the possible evolutionary origins of germ plasm and the role of the oskar gene in this process., oskar is both necessary and sufficient for specifying functional germ cells in Drosophila, and was previously thought to have evolved in a last common Holometabolous ancestor. Here we show that oskar evolved before the divergence of higher insects, may have played an ancestral role in nervous system development, and that its role in germ cell specification is a recent evolutionary innovation.?

The coordination of growth within and between organs in *Drosophila*

Alexander Shingleton[1], Nathan Parker[2], Takashi Hayashi[3], Sasha Makohon-Moore[4]

[1]Michigan State University, U.S.A., [2]Michigan State University, U.S.A., [3]National Institute of Genetics, Japan, [4]Michigan State University, U.S.A.

The developmental mechanisms by which growth is coordinated among developing organs are largely unknown and yet are essential to generate a correctly proportioned adult. In particular, such coordinating mechanisms must be able to accommodate perturbations in the growth of individual organs caused by environmental or developmental stress. By autonomously perturbing the growth of the wing imaginal discs within Drosophila larvae we show that growing organs are able to signal localized growth perturbation to other organs in the body and slow their growth also. Growth rate is so tightly coordinated among organs that they all show approximately the same reduction in growth rate as the developing wings, thereby maintaining their correct size relationship relative to one another throughout development. The same phenomenon is observed among developmental compartments within the wing imaginal disc when anterior compartment is growth-perturbed relative to posterior compartment and vice versa. Recent research has demonstrated that the signal produced by the growth-perturbed discs is an insulin-like peptide (dILP8). Here we present data to demonstrate that ecdysone is also a key player in coordinating organ growth. Our data suggest that ecdysone and insulin signaling work together to synchronize growth and development among organs.

Comparative systems-level studies of appendage morphogenesis using the crustacean model *Parhyale hawaiensis*

Anastasios Pavlopoulos[1], Carsten Wolff[2], Pavel Tomancak[3]

[1]Max Planck Institute of Molecular Cell Biology and Genetics, Germany, [2]Humboldt-Universitaet zu Berlin, Germany, [3]Max Planck Institute of Molecular Cell Biology and Genetics, Germany

A major challenge in biology is to understand how dynamic patterns of gene activity control dynamic cell behaviors to generate organ diversity during development and evolution. We have focused on arthropod appendages that develop particular shapes and sizes to suit the lifestyle of the organisms. Among arthropod models, the crustacean Parhyale hawaiensis offers a unique capacity for microscopic live imaging and tracking of all cells of developing appendages continuously from early specification up to late differentiation. Parhyale embryos undergo direct development from fertilized eggs into miniature adults within ten days, they are transparent and amenable to all sorts of embryological and functional genetic manipulations. Most importantly, each embryo exhibits a remarkable morphological gradation along the anterior-posterior body axis developing a series of different types of appendages adapted for specialized functions. This offers the great advantage to study how morphogenetic mechanisms are deployed differentially in these neighboring growing appendages to produce their differences in size, shape and pattern. Using Selective Plane Illumination Microscopy, we image appendage development at single-cell-resolution in transgenic Parhyale embryos expressing fluorescent tracers. Using these time-lapse recordings, we generate and compare the cell lineages of serially homologous appendages and quantify the cell behaviors that that account for their morphological differences. Finally, we plan to investigate at single-cell resolution with engineered BAC reporters how developmental regulatory genes guide distinct cell behaviors to control appendage morphogenesis. Our integrated approaches allow to study tissue and organ morphogenesis at many levels of biological organization, from genes to cells to final organ structure.

Rapid physiological evolution following habitat invasions

Carol Eunmi Lee
University of Wisconsin, U.S.A.

A fundamental unresolved problem regards constraints on adaptation to novel environments. Invasive species provide valuable models to address this problem, as many are relatively unconstrained in penetrating habitat boundaries. Within the past century, the copepod Eurytemora affinis has invaded freshwater habitats multiple times independently from saline sources. To dissect evolutionary responses during these independent habitat invasions, my laboratory has been integrating analyses of physiological function with comparative functional genomics. We analyzed evolutionary shifts during invasions for pairs of ancestral saline source and derived freshwater populations across four independent invasions from two genetically distinct clades. We found evolution of increased body regulation accompanying freshwater invasions, as evinced by evolution of increased hemolymph osmolality in the freshwater populations. Physiological data revealed shifts in ion retention/integument permeability and changes ion-motive ATPase activity in freshwater relative to saline populations. Most notably, ancestral saline populations selected for freshwater tolerance in the lab recapitulated the adaptive shifts in V-type H+ ATPase activity observed in natural populations. V-type H+ ATPase localization and activity has been hypothesized to be critical for the invasion of fresh water, and perhaps land, but no previous study had demonstrated evolution of function of V-type H+ ATPase. Moreover, the repeatability of evolutionary events, across multiple independent invasions in the wild and selection experiments in the laboratory, indicates the evolutionary lability of this trait. Our findings are consistent with the evolution of increased physiological regulation accompanying transitions into stressful environments.

The development and evolution of the exaggerated weapons of sexual selection

Hiroki Gotoh[1], Ian A Warren[2], Annika Johns[3], Ian M Dworkin[4], Douglas J Emlen[5], Toru Miura[6], Laura Corley Lavine[7]

[1]Washington State University, U.S.A., [2]Washington State University, U.S.A., [3]University of Montana, U.S.A., [4]Michigan State University, U.S.A., [5]University of Montana, U.S.A., [6]Hokkaido University, Japan, [7]Washington State University, U.S.A.

The morphological diversity of insects is one of the most striking phenomena in biology. Evolutionary modifications to the relative sizes of body parts are responsible for a vast range of body forms. Traits with exaggerated proportions such as the "weapons" of beetles have evolved multiple times among several scarab lineages. Sexual selection has shaped the evolution of male phenotypes in many species in which only the males develop weapons that they use to combat rival males for access to females. As with other sexually-selected traits, many beetle weapons are phenotypically plastic resulting from differences in the nutritional environment experienced by growing larvae. What remains unknown however, are the mechanisms that are responsible for coupling nutrition with the disproportionate growth of beetle weapons. Here, we demonstrate the significant roles of endocrine pathways for coupling nutrition with growth, from two case studies in horned beetles ? the Asian rhinoceros beetle Trypoxylus dichotomus and the stag beetle Cyclommatus metallifer. In T. dichotomus, we focus on the insulin signaling pathway as a candidate pathway for condition-dependent growth. RNAi gene-knockdown of the T. dichotomus insulin receptor (InR) resulted in a significant decrease in the weapon size of males. In C. metallifer, another important insect endocrine factor, juvenile hormone (JH) was analyzed. JH titer measurements revealed positive correlations between prepupal JH titer and future mandible size of males. Ectopic application of JH analog to the male stag beetle induced spectacular mandible- specific growth resulting in disproportionate overgrowth of this structure compared to other morphological traits.

Population dynamics of populus leaf miner *Lithocolletis populifoliella* Tr. in

Abbas Hosseinzadeh[1], Zahra Hashemi Khabir[2], Negar Alioghli[3], Nouraddin Shayesteh[4]

[1]Mahabad Branch, Islamic Azad University, Iran, [2]Agricultural and Natural Resources Research Center of West-Azerbaijan province, Iran, [3]Plant Pests and Diseases Research Laboratory of East-Azerbaijan Province, Iran, [4]Mahabad Branch, Islamic Azad University, Iran

Lithocolletis populifoliella Tr. is one of the most important pests of Populus plantations in West Azerbaijan province. Activity of this pest has been noticeable on different clones of Populus species, during recent years. This survey was carried out in order to determine the density and activity of L. populifoliella on 10 clones of Populus (Populus nigra and P. eauramericana) in Populus research station of Mahabad, during 2009 and 2010. The clones were cultured in RCBD (within 3*3 meters distance), in three replications (75 samplings from each clones in three replications). From early April to late September every 10 days and, due to removal of additional effects, 16 samplings out of 25 in each replicate were selected. The number of L. populifoliella larvae was counted on four thirty-centimeter-long branches in four cardinal directions. Statistical analysis indicated significant difference between treatments in terms of number of larvae on the Populus clones. Results showed that the highest and the lowest density of L. populifoliella were recorded on Populus nigra 63/135 and P. eauramericana 488, respectively. This pest produces two generations per year in West Azerbaijan province. The peak of population in 2009 was observed in mid-June for the first generation and mid-July for the second generation of this pest. The peak of population in 2010 due to warm condition for the first and second generations of L. populifoliella was observed in early and late June, respectively.

Diverse developmental and genetic mechanisms direct convergent evolution of a reproductive fitness trait in *Drosophila*

Delbert Andre Green, II[1], Didem Pelin Sarikaya[2], Abel Assefa Belay[3], Aisha Dorta[4], Abha Ahuja[5], Cassandra Gabrielle Extavour[6]

[1]Harvard University, U.S.A., [2]Harvard University, U.S.A., [3]Harvard University, U.S.A., [4]Harvard University, U.S.A., [5]Harvard University, U.S.A., [6]Harvard University, U.S.A.

Convergent morphologies often arise due to similar selective pressures in independent lineages. It is poorly understood whether the same or different developmental genetic mechanisms underlie such convergence. Here we show that independent evolution of a reproductive trait, ovariole number, has resulted from changes in distinct developmental mechanisms each with a different underlying genetic basis in Drosophila. Ovariole number in Drosophila is species-specific, highly variable, and largely under genetic control. Convergent changes in Drosophila ovariole number have evolved independently multiple times within and between species. We show that the number of a specific ovarian cell type, terminal filament (TF) cells, determines ovariole number. We further examine TF cell development in different Drosophila lineages that independently evolved a significantly lower ovariole number than the D. melanogaster Oregon R strain. We show that in some lineages, fewer somatic gonad precursors are established during embryogenesis, resulting in lower ovariole number. In contrast, in other lineages, changes in somatic gonad cell morphogenesis during larval development lead to changes in ovariole number. Evolution at the InR and bab loci has been implicated in previous analyses of genetic changes associated with evolutionary variation in ovariole number. We show that mutations in the D. melanogaster Insulin Receptor (InR) alter gonad primordium size but not ovarian morphogenesis, while targeted loss of function of bric-a-brac 2 (bab2) affects morphogenesis without changing gonad primordium size. Thus, evolution can produce similar ovariole numbers through distinct developmental mechanisms, likely controlled by different genetic mechanisms.

Cytoneme-mediated delivery of hedgehog regulates the expression of bone morphogenetic proteins to maintain germline stem cells in *Drosophila*

Acaimo Gonzalez Reyes[1], Isabel Guerrero[2], Patricia Rojas-Rios[3]

[1]Spanish National Research Council (CSIC), Spain, [2]Spanish National Research Council (CSIC), Spain, [3]Spanish National Research Council (CSIC), Spain

Stem cells reside in microenvironments, or niches, which often contain support cells that control stem cell maintenance and proliferation. Hedgehog (Hh) proteins mediate homeostasis in several adult niches, but a detailed understanding of Hh signalling in stem cell regulation is lacking. Studying the Drosophila female germline stem cell (GSC) niche, we show that Hh acts as a critical juxtacrine signal to maintain the normal GSC population of the ovary. Hh is produced in cap cells, a type of niche support cells and it is then secreted to a second, adjacent population of niche cells, the escort cells, where it activates transcription of the GSC essential factors Dpp and Gbb. In wild-type niches, Hh protein decorates short filopodia that originate in the cap cells and that are functionally relevant, as they are required to transduce the Hh pathway in the escort cells and to maintain a normal population of GSCs. These filopodia, reminiscent of wing disc cytonemes, grow several fold in length if Hh signalling is impaired within the niche. Because these long cytonemes project directionally towards the signalling-deficient region, cap cells sense and react to the strength of Hh pathway transduction in the niche. Thus, the GSC niche responds to insufficient Hh signalling by increasing the range of Hh spreading. Although the signal(s) perceived by the cap cells and the receptor(s) involved are still unknown, our results emphasise the integration of signals necessary to maintain a functional niche and the plasticity of cellular niches to respond to challenging physiological conditions.

Laminins are required for proper formation and maturation of eggs in *Drosophila*.

Maria Dolores Martin Bermudo[1], Maria del Carmen Diaz de la Loza[2], Acaimo Gonzalez Reyes[3]

[1]Spanish National Research Council (CSIC), Spain, [2]Spanish National Research Council (CSIC), Spain, [3]Spanish National Research Council (CSIC), Spain

Drosophila eggs arise from multicellular units known as egg chambers. Each egg chamber consists of a germline cyst surrounded by an epithelium of somatic follicle cells (FC), the follicular epithelium (FE). Egg chambers are initially spherical and elongate dramatically along their anterior-posterior (A-P) axis as they develop. This shape change is important to allow mature eggs to be laid. The elongation process coincides with a planar polarization of the FE and the formation of parallel arrays of actin bundles at the basal surface of FCs. These bundles align with one another perpendicular to the A-P axis, mirroring components of an extracellular matrix (ECM) in the adjacent basement membrane. Egg chambers spin around their A-P axis during elongation, which is required to lay down the polarised ECM. The current model is that this circumferential organization of structural molecules around the egg chamber acts as a molecular corset to promote elongation. Mutations in ECM components, such as Collagen IV or Perlecan, and their receptors, such as integrins, result in round eggs, demonstrating that cell-ECM interactions are required for egg chamber elongation. However, the molecular and cellular mechanisms by which these interactions control egg chamber elongation remains poorly understood. Here, we provide evidence for a function of laminins in the formation and maintenance of a basal polarised ECM and in the proper spinning of egg chambers. These findings highlight a role for the ECM in shaping tissues, which is critical for many morphogenetic processes, such as the formation of mature eggs.

Steroids and miRNAs cooperate in regulation of the stem cell niche

Halyna R Shcherbata
Max Planck Institute for biophysical chemistry, Germany

The adult stem cells in the female ovary of Drosophila provide an excellent model to study germline stem cell niche interactions. Previously it has been shown that in Drosophila steroid hormones are required for the progression of oogenesis during later stages of egg maturation. Furthermore ecdysteroids regulate niche formation and the early differentiation of a germline stem cell daughter. In the absence of these hormones, the developing cystoblasts are blocked in a single cell state which can be overcome by ecdysone supply. Interestingly, ecdysone signaling cell-autonomously modulates the strength of TGF-β signaling in the germline, and also non-autonomously coordinates crosstalk between germline and escort stem cell progeny via cell adhesion. The specificity of this systemic signaling is achieved as a result of spatial expression of EcR/USP co-activators and repressors. Now we also show that the response to ecdysone signaling is modulated via miRNAs. Not only is the expression of these miRNAs dependent on ecdysone signaling during development, but in turn miRNAs target tissue specific ecdysone co-regulators in a regulatory feedback loop.

Hormonal coordination of niche formation with germ line stem cell establishment

Dana Gancz[1], Tamar Lengil[2], Lilach Gilboa[3]
[1]Weizmann Institute of Science, Israel, [2]Weizmann Institute of Science, Israel, [3]Weizmann Institute of Science, Israel

In a Drosophila ovary, somatic niches and germ line stem cells (GSCs) form functional units that continually produce eggs. We show that ecdysone receptors coordinate GSC unit formation. In particular, ecdysone is required for niche formation, and at the third larval instar for the differentiation of primordial germ cells (PGCs, the precursors of GSCs) into germ line cysts. Thus, similar to the mammalian hypothalamus-pitutiary-gonadal axis, the initiation of oogenesis in drosophila depends on a brain-gland-gonad axis. The ecdysone receptors EcR and Usp are expressed in the somatic cells of larval ovaries. At early larval stages, EcR and Usp repress somatic niche formation and PGC differentiation. This early repression allows both niche and GSC precursors time to proliferate, and is required for correct positioning of larval GSC units. The early repressive function of EcR and Usp results in repression of the Broad-Z1 isoform. At late larval stages, EcR and Usp are positively required for Broad-Z1 expression, for niche formation, and for PGC differentiation. In broad mutants, or upon somatic expression of a dominant negative form of EcR, niches and PGCs fail to differentiate. Temporal studies reveal that ecdysone affects PGCs and niches sequentially, and in parallel. In summary, ecdysone receptors are major coordinators of ovary formation by their dual role as early repressors, and later as activators of Broad expression. ecdysone signaling in the ovary is one example of how a single signaling pathway might control niche formation, establishment of its resident stem cells and the initiation of their differentiation.

Insulin signaling: A tangled web controlling reproduction and aging in the mosquito

Michael A Riehle[1], Jenya Antonova-Koch[2], Anam Arik[3], Kendra Quicke[4], Lewis Vibul Hun[5]

[1]University of Arizona, U.S.A., [2]University of Arizona, U.S.A., [3]University of Arizona, U.S.A., [4]University of Arizona, U.S.A., [5]University of Arizona, U.S.A.

The insulin signaling cascade regulates a variety of physiological processes in insects, including metabolism, lifespan, immunity and reproduction. In the mosquito, an understanding of how insulin signaling regulates these processes could provide us with novel target for controlling disease transmission. The role of insulin signaling on mosquito reproduction occurs at multiple levels. Insulin signaling has been implicated in controlling steroidogenesis in ovarian follicle cells and vitellogenesis in the fat body. However, the reproductive role of insulin signaling in the midgut, if any, has not been elucidated. To further assess the role of insulin signaling on mosquito reproduction we genetically engineered Aedes and Anopheles mosquitoes with increased insulin signaling in the fat body, midgut and ovary. This was accomplished by inserting a myrstoylated form of Akt regulated by the vitellogenin, carboxypeptidase, or an ovary specific promoter respectively. Reproduction was assessed during multiple blood meals between transgenic mosquitoes and non-transgenic sibling controls. Mosquitoes overexpressing myrAkt in the midgut or fat body had no significant change in egg production, although vitellogenin transcript expression increased in the fat body. However, mosquitoes overexpressing Akt in the ovary had a small, but significant increase in egg production. By modifying insulin signaling in key reproductive tissues it may be possible to manipulate the mosquito's life history, including reproduction and lifespan.

The Hippo pathway in panoistic ovaries

Maria Dolors Piulachs[1], Paula Irles[2]
[1]*Institute of Evolutionary Biology (CSIC-UPF), Spain,* [2]*Institute of Evolutionary Biology (CSIC-UPF), Spain*

Drosophila melanogaster, the classical model of meroistic ovaries, has been deeply studied in the past years. Hovewer, few information is available about the molecular mechanisms regulating oogenesis in panoistic ovaries. In an attempt to afford data on this primitive ovarian type, we work on Blattella germanica, a cockroach species having panoistic ovaries where only the basal oocyte is developed in each gonadotrophic cycle. In the long term, our interest is to understand the evolutionary transition between panoistic and meroistic ovary types. As the hippo pathway is conserved in all organisms studied to date, it can be a suitable model to afford data on the evolution of these two ovary types. Ovarian transcriptomes obtained in our research group throws us most of the components of the hippo pathway, and we have studied the mRNA expression pattern, and the function of the hippo core pathway in the regulation of the follicular epithelium using RNAi techniques. Our results show that in ovaries with hippo components depleted, the stalk cells in the follicle lost their fate, probably by affecting Notch signalling. In addition, in the follicular epithelium we observed cell over-proliferation and the formation of a double layer of cells. These results are consistent with the previous studies in the meroistic ovary of D. melanogaster, thus suggesting that the function of hippo pathway is generally conserved in insect ovaries.

Development and Reproduction

Designing of a virus-regulated mosquito lethal gene

Margareth Lara Capurro
University of Sao Paulo, Brazil

Dengue fever ranks as the most important mosquito-borne viral disease in the world. Incidence has increased 30-fold in the last 50 years. An estimated 2.5 billion people live in endemic locales and as many as 50 million infections occur annually with 500, 000 cases of dengue hemorrhagic fever and 22,000 deaths. The number of countries reporting dengue hemorrhagic fever has increased more than four-fold since 1970. Vaccines to protect human populations from dengue infection do not exist and insecticide resistance has hampered efforts in vector control 1. These circumstances emphasize the urgent need for alternative approaches to control the transmission of dengue worldwide. The goal of this project was to generate transgenic Aedes aegypti mosquitoes that die upon infection with dengue virus, interrupting virus replication and transmission. This species is the major vector in the majority of dengue epidemics2. These mosquitoes will be of value to public health programs charged with controlling dengue epidemics. The key components of this strategy are the NS3 viral protease, a heat=shock minimal mosquito promoter, and an engineered anti-dengue gene (ADG). The ADG encodes a fusion protein with a transmembrane-endoplasmic reticulum (ER) localization signal, a cleavage site recognized by the viral protease and the complete open reading frame (ORF) of michelob_x (mx), the mosquito orthologue of the reaper/grim-like inhibitor of apoptosis protein (IAP) antagonist genes that have a pivotal role in cell death regulation in Drosophila. The 3'UTR of the transgene will include a SV40 polyadenylation signal to stabilize the transcript.

Promotor sequences of two vitellogenin genes and transcription regulations by JH/20E and endocrine disruptors

Makio Takeda[1], Azza Elgendy[2], Yoshiki Nagaba[3]
[1]Kobe University, Japan, [2]Kobe University, Japan, [3]Kobe University, Japan

The American cockroach, Periplaneta americana has two vitellogenin genes, Vg1 and Vg2. We analyzed the promotor sequence of these genes and identified transcription mediator binding sites by sequence analyses and Luciferase reporter construct: the 935 bp Vg1 promotor contained 1 RXR, 1E74A, 3 JHRE, 2 E75, 1 EcRE and DR2 sites, while the 1804 bp Vg2 promotor contained 2 E74A, 4 JHRE, 1 RXR, 1E75, 2 EcREand 2 DR2.The reporter constructs showed the effect of JHIII and 20 E on the transcrpition activities for both vitellogenin genes. JHIII was stimulatory but 20E was in general inhibitory.Since there are other lipid factor- and transcription momulator-binding sites are present, there is a possibility that some endocrine disruptors may bind these enhancer silencer elements. The Vg1 promotor has an-E box that is a binding site of PAS proteins that include Methoprene resistant(Met) through whicj JHIII may acts. PAS stands for Per-Arnt-Single-minded and Arnt is a arylhydrocarbon receptor (AHR)-nuclear translocator. Therefore, this class of endocrine disruptors may bind the E-box, as well as the circadian transcription regulators such as CYC or CLOCK may also affect.We have already shown that four representative endocrine disruptors siverely affect the vitellogenin gene transcription in the giant water bug, a red-data species in Japan (Nagaba et al., 2011 J.Insect Conservation 15, 421) and now examine the possibility of using this promotor for monitoring environmental pollutants that work as endocrine disruptors as well as JHIII receptor.

Cell competition and compensatory cellular hypertrophy in nonproliferating tissue

Yoichiro Tamori[1], Wu-Min Deng[2]

[1]Florida State University, U.S.A., [2]Florida State University, U.S.A.

Cell competition, a struggle for existence between cells in heterogeneous tissues, is an intrinsic homeostasis system through which normal cells sense and remove aberrant (e.g. precancerous) ones, to maintain tissue integrity in multicellular organisms. Elimination of suboptimal loser cells is accompanied by 'compensatory proliferation' of winner cells. As a result, cell competition not only eliminates potentially deleterious cells during development but also assures that final organ size is properly controlled. So far, cell competition has only been found in tissues where cells undergo proliferation. Speed of proliferation is generally accepted as the primary criterion determining winner and loser cells, but here we report that cell competition can also occur between nondividing cells with different genetic backgrounds. In nonproliferating Drosophila follicular epithelia, we found that Minute heterozygous or mahjong homozygous mutant cells were eliminated by their wild-type neighbors through cell competition. The winner cells did not undergo compensatory proliferation but instead underwent 'compensatory cellular hypertrophy' to compensate loss of loser cells. This hypertrophy was implemented by acceleration of the endoreplication cycle. Moreover, we found that elimination of the loser cells required upregulation of JNK signaling and that endocycle acceleration involved upregulation of insulin/insulin-like growth factor-like signaling, both in the winner cells. These studies revealed a novel tissue-homeostasis strategy in nondividing tissue: elimination of potentially deleterious cells through cell competition and repair of the tissue through compensatory cellular growth

Micro RNAs in the control of the differential development of *Apis mellifera*

Zila Luz Paulino Simoes
Faculdade de Filosofia Ciencias e Letras RP - USP, Brazil

Apis mellifera queens and workers are prime examples of how deeply the environment could affect ontogenesis. In bees, a differential protein-containing diet is responsible for the high levels of juvenile hormone (JH) observed in queens, which, in turn, directs larval development and the morphological differences observed in both castes. The differential levels of JH is controlled by a specific enzyme the juvenile hormone esterase (JHE). The JH activation of physiometabolic gene cascades allowed queens to grow differentially and be an efficient egg laying machine. However, in the presence of low levels of JH, honeybee workers develop characters transforming them in highly specialized member of the colony, active pollinators with extraordinary cognitive capacity. Aiming to shed some light on JHE role in caste development and differentiation we interfered its codifying gene using RNAi. We conducted an experiment treating 3 groups of young larvae (L2) with Amjhe dsRNA and leaving other 3 groups developing without treatment, both until pre-pupal phase. The miRNA of the six groups were deep sequenced using Illumina Technology. We observed that the miRNA gene family differ profoundly between the treated and untreated groups. We selected 14 miRNAs and searching for their targets (RNAHybrid) we found approximately 1100 candidates (affected genes). Looking for the Ortologs we note that preferentially developmental genes were affected, indicating that the more expressed miRNA are inhibiting the characteristic worker developmental genes directing the development to queen like. Confirming our hypothesis that JHE is in the regulation of caste differentiation. Financial support: FAPESP

The influence of juvenile hormone on the social physiology of bumble bees (*Bombus terrestris*)

Hagai Shpigler[1], Adam Siegel[2], Christina M Grozinger[3], Guy Bloch[4]

[1]Hebrew University of Jerusalem, Israel, [2]Hebrew University of Jerusalem, Israel, [3]Hebrew University of Jerusalem, U.S.A., [4]Hebrew University of Jerusalem, Israel

Juvenile hormone (JH) signaling is inhibited in the presence of the queen in both honey bees and bumble bees. However, in honey bees, JH regulates age- related division of labor whereas in bumble bees JH titers are correlated with ovarian development. Thus, the pathways downstream JH are predicted to at least partially diverge in order to accommodate the different functions in the two species of bees. We found that allataectomized Bombus terrestris workers do not develop their ovaries even under queenless conditions that typically promote worker reproduction. This effect was reversed by replacement therapy, confirming the gonadotropic function of JH. Similar manipulations of JH signaling also influenced metabolism, wax secretion, and fat body development. Hemolymph JH titers did not differ between nurses and foragers suggesting that JH does not regulate division of labor in bumble bees. We further examined the expression patterns of a transcription factor, Kruppel-homolog 1 (Kr-h1) in bumble bees. Kr-h1 expression is downregulated in honey bee workers upon exposure to the queen pheromone, and upregulated in foragers. In the bumble bee, Kr-h1 levels were similarly downregulated in the presence of the queen or dominant workers. Kr-h1 levels were also associated with JH-mediated changes in reproductive state, but elevated levels were not associated with foraging behavior. These results suggest that Kr-h1 is a part of a JH signaling pathway that is important for social regulation, but was differentially co-opted during the social evolution of bumble bees and honey bees.

Transcriptional control of ovary size - cell death in the ovary of honey bee worker larvae

Klaus Hartfelder[1], Fernanda Carvalho Humann[2], Gustavo Jacomini Tiberio[3]
[1]University of Sao Paulo - FMRP, Brazil, [2]University of Sao Paulo - FMRP, Brazil, [3]University of Sao Paulo - FMRP, Brazil

Divergent development of the ovary phenotype of honey bee queens and workers starts from a bipotential larval state, with each ovary comprising 150-180 ovariole primordia. In queens, all develop into functional ovarioles, whereas programmed cell death in the fifth larval instar eliminates 95-99% of these in workers. To understand underlying molecular mechanisms we generated suppression subtractive hybridization libraries, giving a total of 136 unique sequences. 72 % of the queen library sequences represented known or predicted genes, leaving 28% as unpredicted, in contrast with the worker library where 59% represented unpredicted genes. A set of 16 sequences was chosen for expression analysis by quantitative RT-PCR. Statistically significant expression differences were denoted for a short chain dehydrogenase/reductase gene overexpressed in workers, an ornithine amino transferase gene overexpressed in queens, and two ESTs representing unpredicted genes, both located in chromosome 11. Complete CDSs for the latter, obtained by 3'5'RACE, revealed that neither contained an ORF of significant length. RNA secondary structure analysis confirmed both as putative long non coding RNAs, these named lncov1 (overexpressed in workers) and lncov2 (overexpressed in queens). In the honey bee genome, lncov1 maps within an intron of a predicted gene of unknown function, whereas lncov2 is intronic to fringe. Importantly, both genes are located within the previously identified chromosome 11 QTL for ovariole number variation in bees. This is the first evidence for a potential role of long non-coding RNAs in the developmental regulation of a socially relevant reproductive trait. Financial support by FAPESP

The i5K pilot genome sequencing at the Human Genome Sequencing Center.

Stephen Richards
Baylor College of Medicine, U.S.A.

The i5K is an initiative to sequence the genomes of 5,000 arthropods of medical, agricultural and scientific importance. As a pilot project to identify potential problems and challenges in species selection, identification and acquisition, DNA isolation, sequencing strategies and assembly, automated and manual annotation, analysis and publication, the BCM-HGSC is sequencing ~30 arthropods, selected by the i5K species selection committee. Our extensive experience in arthropod genomics, has allowed us to quickly identify new challenges in scaling the number of de-novo genome projects. For example, many arthropod species have much larger genome sizes than initially expected. For a number of arthropod orders, small body sizes yield tiny amounts of DNA. Other challenges include the inability to inbreed, a common situation for most arthropods or sex individuals ? for example arthropods where only larvae can be easily collected. An additional challenge is to identify ongoing genome projects to avoid replication of work. This challenge will become increasingly important as the reduction in sequencing cost leads to a rapid increase in genome sequencing projects. We present our success in working with community groups to select appropriate species for sequencing, our Illumina sequencing plans, and initial assembly demonstration results, our proposed modifications for extremely low quantities of DNA, and our automated analysis plans. Also we present an outline of the i5K community annotation and analysis process. Most importantly the i5K project is establishing a genomic molecular baseline to the study of animals that affect our society so greatly.

Genetics, Genomics and Evolutionary Entomology

The arthopod genomics revolution

Xin Zhou
BGI, China

The assembly of a new genome opens the door for scientific exploration on the focal species at a whole new level. Although a series of arthropod genomes have been published or close to finishing, the available genomes are significantly biased towards just a few lineages. For example, all published insect genomes are from just 6 orders, most of which belong to holometabolans. The under representation for the majority of arthropod lineages is mainly due to difficulties in current sequencing technologies and informatics in dealing with large and complex genomes. In this presentation, I will introduce the current progress in arthropod genomics research at the BGI. The genomes of a number of insect species, including those with relatively high levels of heterozygosity and repeat sequences, have been successfully assembled using a strategy combining whole genome shot-gun and fosmid-to-fosmid sequencing. In the mean time, large-scale international collaborations synergizing research expertise and resources are coordinated by the BGI. For example, a new initiative aiming to catalogue genomic features of the species and populations of global Daphnia is being developed by the BGI and the Daphnia Genomics Consortium (DGC). Biological materials, including living animal stocks, and a whole spectrum of genomic data, accompanied by detailed records of morphological/biological/ecological/toxicological traits, will be generated through this international collaboration and made available to the community. Through this effort, we hope to gain a better understanding of the genomic mechanism underling the rapid adaptation to environmental changes and evolutionary patterns in Daphnia.

Molecular regulatory mechanism of phase change in locusts

Le Kang
Chinese Academy of sciences, China

The migratory locust is a notorious agricultural pest species around the world. The individuals of the locusts exhibit remarkable phenotypic plasticity, termed "phase change", in response to local population density. The gregarious locust populations often intrigue plagues and cause large economic losses in agriculture. Molecular mechanism of phenotypic plasticity that contributes to mass swarming remains unknown. Here, a genome-wide screening by oligo-nucleotide microarray was used to study the gene expressions in time-courses of solitarization and gregarization, as well as at different nymph stages in two extreme phases. Several CSP genes and one takeout gene, which have higher expression levels in gregarious and solitarious locusts respectively, significantly displayed opposite expression trends during time courses. RNA interference and olfactory behavioral experiments confirmed the CSP and takeout genes involved in the shift of attraction/repulsion behavior. Stadium-by-stadium comparison between two phases revealed that genes pale, tan, ebony and henna are more active in gregarious phase than in solitary phase, and vice versa for hexamerin and JHBP. Repression of gene sets (pale, ebony and VAT1) in dopamine metabolic process by pharmacological agents or RNA interference in gregarious hoppers induced solitary behavior, whereas L-DOPA-injected solitary hoppers exhibited gregarious-like behavior. These findings suggest that olfaction-related genes initiate the behavioral phase change and genes in dopamine pathway maintain behavioral and body color traits in the two phases.

Genetics, Genomics and Evolutionary Entomology

What Nasonia Genomes Reveal about Adaptation & Speciation

John H Werren
University of Rochester, U.S.A.

The genetic bases of morphological, developmental and behavioral differences between species are still largely unknown. Genomics now provides a means for uncovering genetic and molecular mechanisms of species divergence in diverse "emerging model" systems. A challenge still remains - going from individual quantitative trait loci (QTL) to identifying the precise genes and sequences causing a trait difference. Described here are successful efforts to identify QTL causing growth differences among species of the insect Nasonia. Nasonia is a complex of closely related species that differ in male wing size. Nasonia has genome sequences for the species, interfertile hybrids, and short generation time assist. Exploiting these genetic advantages, we have cloned two major QTL causing species growth differences. One is a QTL causing ~40% increase in wing growth and maps to the cis-regulatory region of the master sex determination gene doublesex (dsx). The second major QTL causes an increase in male wing width through increases in cell number and size. Fine-scale mapping and in situ hybridization reveals changes in at least three (non-coding) regions around the growth gene unpaired (upd) cause spatial/temporal change in expression of upd and growth of the developing wing. Upd is believed related to the growth regulator interleukin-6 in vertebrates. These findings support the view that cis-regulatory changes in functionally conserved developmental genes are targets for morphological evolution. The results also illustrate how genomic tools can rapidly advance new systems for studies of basic biological processes.

An integrative approach applied to the phenotypic plasticity of the pea aphid

Denis Tagu[1], Fabrice Legeai[2], Julie Jaquiery[3], Lucie Mieuzet[4], Frederique Maheo[5], Nathalie Prunier[6], Joel Bonhomme[7], Pierre Nouhaud[8], Claude Rispe[9], Oscar Gaggiotti[10], Remi Houlgatte[11], Solenn Stoeckel[12], Jean-Christophe Simon[13]

[1]INRA, France, [2]INRA, France, [3]INRA, France, [4]INRA, France, [5]INRA, France, [6]INRA, France, [7]INRA, France, [8]INRA, France, [9]INRA, France, [10]CNRS, France, [11]INSERM, France, [12]INRA, France, [13]INRA, France

Sequencing a genome is a first step of a great adventure: such like anatomy which is required for understanding physiology, sequencing a genome is necessary for discovering the complex processes of genome regulation for individual and species adaptation. All these processes (anatomy and functioning of a genome) are collective and require a strong community working together. A summary and updates on the pea aphid genome story driven by the International Aphid Genomics Consortium will be given. Then, examples of what has been done in our lab using these genomic resources will be presented: we aim at integrating population genomics, quantitative genetics and transcriptomics to get comprehensive insights into the variations of reproductive mode in aphids, by linking phenotypic plasticity (molecular bases of clonal and sexual phases within a given genotype) and polymorphism (co-existence of sexual and asexual lines within a given species). We detected genomic regions that have evolved under divergent selection whether populations reproduced asexualy or sexualy one time per year. We identified 5 quantitative trait loci (QTLs) linked to the reproductive mode in the pea aphid, among which one region was also detected to have evolved under divergent selection between sexual and asexual populations. This region contains sequences related to the juvenile hormone pathway and transcriptomic analyses by RNA-Seq are underway to assess their potential involvement in the determination of reproductive strategies. These integrative approaches could not be performed without a prior join effort of a whole community.

Genetics, Genomics and Evolutionary Entomology

DNA methylation variation among morphs of the pea aphid, *Acyrthosiphon pisum*

Owain Rhys Edwards[1], Denis Tagu[2], Jennifer Brisson[3], Stephanie Jaubert-Possamai[4]

[1]CSIRO, Australia, [2]INRA Rennes, France, [3]University of Nebraska, U.S.A., [4]INRA-Antibes, France

Aphids display extraordinary polyphenism, in which discrete alternative phenotypes are produced in response to environmental cues. From the same genetic background, various morphs are generated differing in their morphology, physiology and behaviour. In this study, DNA from aphid heads was used to compare the methylomes of three aphid morphs of the same clonal lineage (LSR1): Unwinged asexual females (viviparous apterae), winged asexual females (viviparous alatae), and unwinged sexual females (oviparous apterae). Averaged across all genes, all morphs showed similar levels and patterns of CG methylation across gene bodies, with consistently higher levels of methylation in exons and lower levels in introns. In contrast, the levels of CHG and CHH methylation were more variable among the morphs, and a pattern of increased intron-specific methylation was observed in the sexual morph. RNASeq analysis was used to associate observed differences in DNA methylation between morphs with variation in expression and splicing of individuals genes. The implications of these results in terms of the role of DNA methylation in regulating aphid developmental polyphenism are discussed.

The genome of two spotted spider mite *Tetranychus urticae*

Miodrag Grbic[1], Thomas Van Leeuwen[2], Richard Clark[3], Maria Navajas[4], Yves van de Peer[5], Isabel Diaz[6], Felix Ortego[7], Rene Feyereisen[8], Vojislava Grbic[9]

[1]UWO, Canada, [2]Faculty of Bioscience Engineering, Ghent University, Belgium, [3]University of Uta, U.S.A., [4]UMR CBGP, France, [5]VIB, Technologiepark 927, Belgium, [6]UPM-INIA, Spain, [7]Centro de Investigaciones Biologicas, CSIC, Spain, [8]INRA, CNRS and Universite de Nice Sophia Antipolis, France, [9]UWO, Canada

The two spotted spider mite Tetranychus urticae is a cosmopolitan agricultural pest with an extensive host plant range and an extreme record of pesticide resistance. T. urticae represents one of the most polyphagous arthropod herbivores, feeding on more than 1100 plant species belonging to more than 140 different plant families including species known to produce toxic compounds. It is a major pest in greenhouse production and field crops, destroying annual and perennial crops such as tomatoes, peppers, cucumbers, strawberries, maize, soy, apples, grapes, and citrus. Our international consortium sequenced and annotated spider mite genome, representing the first complete chelicerate genome. At 90 Mb T. urticae has the smallest sequenced arthropod genome. The spider mite genome reveals unique changes in hormonal milieu, organization of the Hox complex, and evolution of silk production. We find strong signatures of polyphagy and detoxification in gene families associated with feeding on different hosts and in new gene families acquired by lateral gene transfer. Deep transcriptome analysis of mites feeding on different plants shows for the first time how this pest responds to a changing host environment. The compact T. urticae genome has unique attributes among arthropod genomes with remarkable instances of gene gains and losses. The completion of the T. urticae genome sequence opens new avenues for understanding the fundamentals of plant-herbivore interactions, developing novel pest management strategies and producing new bionanomaterials.

Regulation of immune genes in silkmoths: From transcriptome to individual genes

Javaregowda Nagaraju
Centre for DNA Fingerprinting and Diagnostics (CDFD), India

The innate immune system defends all metazoans against invading microorganisms. Such a defense mechanism is reported to be well conserved and relies on intricate host-pathogen interaction between pathogen recognition receptors in the host and pathogen associated molecular patterns in microbes. Drosophila and silkworm have been attractive model organisms for the study of immune system due to their well-established genetics, the absence of acquired immune system, and the remarkable correlation of their immune signaling pathways with the mammalian innate immune defense system. One of the hallmarks of the insect defense is systemic response, which involves the synthesis of small cationic antimicrobial peptides by the fat body, a functional equivalent of the mammalian liver. Two distinct and reasonably well-studied signaling pathways, the immune deficiency (Imd) and the Toll pathways, control the transcription of the antimicrobial peptide genes. Fungal or Gram-positive bacterial infections activate the Toll pathway whereas Gram-negative bacterial infection activates the Imd pathway. With the availability of whole genome sequences and RNA interference tool for various insects, many novel immune genes have been identified and their functions have been determined. In the silkmoths, through analysis of immune transcriptome, we have identified and functionally characterized a number of novel immune genes that are involved in nodulation, clearance of Gram-positive bacteria and bacterial growth arrest. Also, we have demonstrated that immune genes are sex-biased in insects. These results would add to further understanding of immune mechanisms in insects and also provide clues to look for similar mammalian proteins whose function is not understood.

Genetics, Genomics and Evolutionary Entomology

Sequencing small and large insect genomes

Hugh M. Robertson
University of Illinois at Urbana-Champaign, U.S.A.

We have sequenced the genomes of three Hymenoptera, and are in the process of sequencing three more, as well as a fly, moth, and beetle. This sequencing is being performed entirely with ILLUMINA with assembly using SOAPdenovo. The three species completed are the dwarf honey bee Apis florea, the common eastern bumble bee in the USA, Bombus impatiens, and the imported alfalfa leafcutter bee, Megachile rotundata. Each of these was performed largely from a single haploid male to avoid polymorphism and resulted in high quality draft genome assemblies of 300-500 Mbp with scaffold N50s in the 500-1000Mbp range. They are currently being annotated and analyzed. The ongoing projects on Hymenoptera are the wheat stem sawfly, Cephus cinctus, and two parasitoid wasps, Microplitis molitor and Diachasma alloeum. Again each is largely being done from single males, but using multiple males and females for mate pairs. The moth genome is that of the navel orangeworm, Amyelois transitella, the fly is the apple maggot, Rhagoletis pomonella, and the beetle is the western corn rootworm, Diabrotica virgifera. Each of these last three is based on inbred populations to reduce polymorphism. The latter two are particularly large genomes, estimated at 1 and 2.6 Gbp, respectively, and are providing a challenge to this approach to relatively cheap insect genome sequencing.

Genetics, Genomics and Evolutionary Entomology

Molecular evolution in social insects

Michael Goodisman
Georgia Tech, U.S.A.

The evolution of sociality represented one of the major transition points in evolutionary history. We are interested in understanding how evolutionary processes affect social systems and how sociality, in turn, affects the course of evolution. The main subjects of our research are the social insects, which display the most advanced levels of sociality and dominate ecological communities because of their sophisticated group behaviors. Our recent research has focused on understanding the molecular underpinnings of social behavior using comparative and functional genomic approaches. I will discuss studies aimed at deciphering how epigenetic inheritance affects the formation of social insect castes. In addition, I will present information on how gene evolution is coupled to phenotypic variation in insect societies. Overall, our research helps link molecular processes to the evolution of advanced societies and phenotypic diversity.

Genetics, Genomics and Evolutionary Entomology

Identification and analysis of conserved elements in social insect genomes

Cai Li
BGI, China

Conserved elements or conserved regions in a genome are the genomic sequences that are highly similar across different species. The sequence conservation in these regions implies they are probably functional elements. As more and more social insect genomes have been sequenced, it is an unprecedented chance to investigate the genomic conservation across different social insect taxa. Based on the multiple whole genome alignments, we use computational methods to identify genomic regions conserved in all sequenced social insect genomes, as well as those conserved in specific groups of social insect genomes (e.g., ant group, bee group, etc). As many of the conserved elements are located in non-coding/unannotated regions, we utilize the available biological databases to annotate these conserved elements. After annotation, we try to identify the functional categories over-represented in the conserved regions and investigate their possible roles in social evolution. This study contributes to the annotation of social insect genomic sequences and sheds light on the conserved regulatory mechanisms of social insects.

Comparative Genomics of Ants

Juergen Rudolf Gadau[1], Lothar Wissler[2], Daniel F. Simola[3]

[1]Arizona State University, Tempe, AZ, 85287, U.S.A., [2]University of Munster, Germany, U.S.A., [3]University of Pennsylvania, U.S.A.

Comparative genomics is a powerful tool to identify functional genomic regions. This includes both coding and conserved non-coding DNA. Additionally, it allows inferring the origin and evolution of novel genes and changes in the amount and distribution of regulatory elements. With the publication of seven ant genomes we are in a unique position to determine genomic changes associated with the convergent evolution of eusociality (bees and ants) and compare evolutionary trends in 11 hymenopteran Genomes with that in 15 Dipteran genomes and 30 arthropod genomes, respectively. Surprisingly, the annotations for all seven ant genomes harbor a huge number of lineage specific genes and the number of lineage specific genes is negatively correlated with phylogenetic distance. Many of those lineage specific genes have expression support and seem to be functional rather than annotation artifacts. I will also discuss the evolution of gene regulation in respect to DNA methylation, conserved and transcribed intergenic RNA's, and transcription factors and transcription factor binding sites.

Identification and characterization of long noncoding RNA in the Locust *Locusta migratoria* reveals roles in phenotypic plasticity regulation

Bing Chen[1], Yi Zhang[2], Xia Zhang[3], Gongxin Peng[4], Le Kang[5]

[1]*Institute of Zoology, Chinese Academy of Sciences, China,* [2]*Institute of Zoology, Chinese Academy of Sciences, China,* [3]*Institute of Zoology, Chinese Academy of Sciences, China,* [4]*Institute of Zoology, Chinese Academy of Sciences, China,* [5]*Institute of Zoology, Chinese Academy of Sciences, China*

Many organisms, including insects, express phenotypic plasticity. The regulatory mechanisms underlying phenotypic plasticity are largely unknown so far. Here we reported one type of RNA molecular, long nonconding RNA (lncRNA), possess such attributes by which to trigger regulation of plasticity in a timely manner because lncRNAs do not need to translate into protein before functioning. A few dozen lncRNAs are known to play important regulatory roles in diverse processes, such as imprinting, epigenetic regulation, and development. In this study on the migratory locust Locusta migratoria, we first developed a new prediction method to identify noncoding RNA with high accuracy and sensitivity (both >91%). Based on EST and RNA-seq transcriptome data, we totally discovered 9406 distinct lncRNA expressed in different tissues and developmental stages. 41% of the lncRNAs are located within intergenic region, and 19% within intronic region. lncRNAs demonstrated high tempo-spatial specificity in expression. We then investigated lncRNAs' role in phase change regulation of the locust. Among these lncRNAs, 859 lncRNAs differentially expressed between solitary and gregarious phases of the locusts. Some lncRNAs exhibit contrasting expression pattern during time-course of isolating and crowding of locust population, imply lncRNAs' role in regulation of phenotypic plasticity.

Genetics, Genomics and Evolutionary Entomology

Genomic consequences of multiple speciation processes in a stick insect

Patrik Nosil
University of Sheffield, United Kingdom

Diverse geographic modes and mechanisms of speciation are known, and individual speciation genes have now been identified. Despite this progress, genome wide outcomes of different evolutionary processes during speciation are less understood. Here, I present an integrative analysis of genomic divergence among populations of Timema cristinae stick insects undergoing ecological speciation. The result stem from a combination of whole genome sequencing, genetic linkage and association mapping, ecological and spatial information, mating trials, manipulative field experiments and analysis of 86,130 SNPs distributed across the genome. I report patterns consistent with effects of numerous factors on genomic divergence, including geographic distance, gene flow, divergence in host-plant use and climate, and selection against maladaptive hybridization (i.e., reinforcement). For example, the number of highly differentiated 'outlier loci', allele-frequency clines, and the overall distribution of genomic differentiation were recognizably affected by these factors. The results demonstrate how genomic data can provide new insights into speciation and how genomic divergence can be complex, yet predictable.

Genetics, Genomics and Evolutionary Entomology

Transposon structure and function in multiple eukaryotic systems

Peter Atkinson[1], Peter Arensburger[2], Robert H. Hice[3], Jennifer A. Wright[4], Nancy L. Craig[5]

[1]University of California, Riverside, U.S.A., [2]University of California, Riverside, U.S.A., [3]University of California, Riverside, U.S.A., [4]University of California, Riverside, U.S.A., [5]Johns Hopkins School of Medicine, U.S.A.

Transposons play a significant role in insect genetics and biotechnology. Insect whole genome projects have revealed the transposon landscape in several insect genomes with some variance in both transposon load and in the numbers of superfamilies present within a species. Despite the larger numbers of transposons present in insects, only six are commonly used for the genetic manipulation of insects, these being P and hobo (virtually exclusively in Drosophila melanogaster in which strains lacking active P and hobo transposons were established several decades ago), piggyBac, Mos1, Minos and Hermes, with piggyBac proving to be the most robust transposon not only in insects but in some protozoa and in some vertebrates as well where, in humans, it is being developed as a gene therapy vector. All these transposons were found in insects, most were discovered through experiments that detected their mobility, and all were found before the advent of whole genome projects. Without question their use in insect genetics and biotechnology has had a great impact on these fields, however we still know little about how endogenous and foreign transposons are regulated in their host cells and we have yet to thoroughly mine insect genomes for new transposons which may have mobility properties different or even superior to the ones now in use. These investigations are facilitated by high throughput sequencing approaches which may enable us, at least in descriptive terms initially, to describe the genomic background in which transposons find themselves both in their original host genome and in new

Transposon-based genetic analysis in *Anopheles stephensi*

David A. O'Brochta
University of Maryland, U.S.A.

Advanced transposon-based genetic technologies are now available for use in Anopheles mosquitoes that provide new opportunities for performing forward and reverse genetic analyses leading to new advances in our understanding of Anopheles gene structure and function. Transposons can configured to carry specific sensors that permit the detection of various genetic elements such as enhancers, promoters and genes. Here I report that the piggyBac transposon in Anopheles stephensi is highly active after initial integration into the genome and can be used in combination with the Gal4/UAS system to efficiently detect enhancers and genes. On average, 1.3% of the progeny arising from enhancer-trap screens harbored an enhancer-detection event. A collection of lines with patterns of Gal4 expression of particular use to vector biologists has been assembled and will be described. In addition, a functional gene-trap system was created based on a promoter-less reporter gene with a 3' splice-acceptor site. This system is functional and being used to conduct forward genetic analyses of salivary gland- and midgut-function in adult females. The availability of these powerful functional genomics technologies in conjunction with currently available structural genomic resources will enhance efforts to investigate the genetic basis of important aspects of mosquito biology. These technologies also provide the vector biology community with new genetic resources.

The complete genomic sequence of the silkworm Bombyx mori was published firstly in lepidopteran insects. The assembly of 432 Mb genome is a reference in the genomic analysis of the very diverse order of Lepidoptera. In post-genomic studies, various genetic tools such as binary expression systems, enhancer traps, gene traps, insertional mutagenesis, gene targeting, and RNAi are useful for analysis of gene function. To develop the versatile genetic tools for various insects is very important. We have been developing the genetic tools using transgenic silkworms for gene functional analysis and new uses. We established the method to generate the transgenic silkworm using piggyBac and Minos transposons. We have constructed some new marker genes. Then we developed the binary expression systems in the silkworm using a GAL4/UAS or Tet-On/Off system. Also we have constructed the piggyBac-based GAL4 enhancer trap and gene trap systems by remobilizing transposon vectors to various chromosomal locations. Such systems can be used for targeted transgene expression in a stage- and organ/tissue-specific manner, and insertion of the transgene may disrupt the endogenous gene, creating a new mutant allele. Several enhancer trap lines were successfully used to determine the function of classical mutants. Recently, we have been developing a gene targeting system using ZFNs and TALENs, in addition to a PhiC31 integrase system. We have also constructed an efficient system for producing recombinant proteins/silks using a transgenic technology and silk-synthesis system of silkworm in the silk gland.

A new hAT-family transposon vector, hopper, from the Oriental fruit fly, *Bactrocera dorsalis*

Alfred M. Handler
USDA, Agricultural Research Service, U.S.A.

The hopper hAT-family transposable element isolated from the oriental fruit fly, Bactrocera dorsalis, is distantly related to both the Drosophila hobo element and the Ac element from maize. The original 3,120 bp element was highly degenerate and appeared to have a mutated transposase, while a second 3,131 bp element isolated from a white eye strain had a transposase reading frame and terminal sequences consistent with function. This putative functional element was used to create a binary vector:helper transformation system by linking the transposase to a D. melanogaster hsp70 promoter, and creating vectors marked with the D. melanogaster mini-white+ gene and polyubiquitin-regulated DsRed markers. Both vectors were used to transform D. melanogaster, and the DsRed vector was used to transform the Caribbean fruit fly, Anastrepha suspensa, indicating a wide range of function in dipteran species. However, transformation frequencies were approximately 5% per fertile G0, which is relatively low compared to other widely used systems for Drosophila and non-drosophilid species.

Genetics, Genomics and Evolutionary Entomology

Site-specific recombination for transgene targeting in tephritid genomes

Marc F Schetelig[1], Alfred M. Handler[2]
[1]*USDA-ARS, U.S.A.*, [2]*USDA-ARS, U.S.A.*

Insect transgenesis is mainly based on the random integration of DNA fragments embedded into non-autonomous transposable elements (e.g. piggyBac, mariner, Minos, etc.). Once a random insertion into a specific location of the genome has been identified as particularly useful in respect to transgene expression, ability to make the insertion homozygous, and lack of fitness costs, one would like to take advantage of that location for further modification and improvement. Efficient methods for the modification of previously inserted transgenes are site-specific integration systems like the attP-attB/ phiC31 system. Such a system can be used to exchange and/or stabilize transgenes in the respective tephritid genome. This will help to combine several transgene-encoded advantageous traits at evaluated genomic positions to generate optimized strains for environment-friendly pest control. Advances in site-specific integration systems in tephritids are shown.

Genetic control of vector-borne pathogens

Anthony A. James
University of California, U.S.A.

Genetic strategies have been proposed to control the transmission of vector-borne pathogens. Approached that seek both population suppression and population replacement of mosquitoes have benefitted from the development of transgenesis, site-specific recombination and targeted effector molecules. Advances in the development of vector-based genetic control strategies for preventing malaria parasite and dengue virus transmission have resulted in tools that in laboratory trials either suppress completely mosquito populations or render them incapable of transmitting the pathogens. Field trails are in progress for some population suppression strains, while the population replacement approaches still require the development of safe and efficacious gene-drive systems.

Disrupting mosquito attraction to host cues by targeted mutagenesis of the orco olfactory co-receptor

Matthew DeGennaro[1], Carolyn S McBride[2], Laura Seeholzer[3], Takao Nakagawa[4], Chloe Goldman[5], Nijole Jasinskiene[6], Anthony A James[7], Leslie B Vosshall[8]

[1]The Rockefeller University, Howard Hughes Medical Institute, U.S.A., [2]The Rockefeller University, U.S.A., [3]The Rockefeller University, U.S.A., [4]Biological Science Laboratories, KAO Corporation, U.S.A., [5]The Rockefeller University, U.S.A., [6]University of California, U.S.A., [7]University of California, U.S.A., [8]The Rockefeller University, Howard Hughes Medical Institute, U.S.A.

Human host odor is a long-range, attractive cue that guides mosquitoes to their hosts. The mosquito perceives differences in host odor, both between and within species, to determine which host to feed upon. The molecular mechanism by which mosquitoes translate host odor information into host-seeking behavior has been inferred but not demonstrated. Insects use two families of olfactory receptors, the Ionotropic Receptor (IRs) and the Olfactory Receptors (ORs), to detect volatile chemicals in their environment. To shed new light on mosquito olfactory-driven behaviors, we developed a technique for targeted mutagenesis in Aedes aegypti using zinc-finger nucleases (ZFNs) and proved that it can work by heritably disrupting GFP. In addition, ZFNs can induce homology dependent repair allowing for genetic modification at a specific site. To understand the role of ORs in mosquito behavior, we targeted orco, a gene formerly known as Or83b in Drosophila and Or7 in mosquitoes, which is an obligate co-receptor for ORs. We demonstrate that Aedes orco is necessary for electrophysiological responses to 1-octen-3-ol but not to CO2. We are currently using olfactometer-based assays to understand how orco null mutant mosquitoes respond to human and non-human host odors, chemical repellents, and plant volatiles. The establishment of loss-of-function genetics in Aedes aegypti will open new paths of investigation in the genetics of vector biology.

Development of 'male-only' strains of the New World screwworm fly, *Cochliomyia hominivorax*

Maxwell John Scott[1], Felix Guerrero[2], Fang Li[3], Azhahianambi Palavesam[4], Agustin Sagcal[5]

[1]North Carolina State University, U.S.A., [2]USDA-ARS, U.S.A., [3]North Carolina State University, U.S.A., [4]University of Maryland, U.S.A., [5]USDA-ARS, Panama

The New World screwworm (NWS) fly, Cochliomyia hominivorax, is a serious pest of warm-blooded animals. The Sterile Insect Technique (SIT) was used to eradicate the NWS from U.S.A., Mexico and Central America. Currently, the USDA-APHIS and the Panamanian government jointly operate a NWS mass-rearing and sterilization facility in Pacora, Panama. Sterilized male and female NWS are released continually in a 'buffer zone' in Southern Panama to prevent re-introduction from South America. APHIS has identified several advantages to incorporating transgenic NWS strains into the control program. These include strains that carry stable fluorescent proteins for monitoring released flies and strains that facilitate the release of only males, which would increase the efficiency of SIT. We are currently developing transgenic NWS strains marked with fluorescent proteins that carry tetracycline-repressible female lethal genetic systems. To achieve sex-specific gene expression we have isolated the transformer (tra) gene from NWS. A conditional female-lethal gene cassette was made consisting of the tetracycline transactivator (tTA) gene interrupted by the NWS tra intron and driven by a minimal promoter with multiple tTA binding sites. Alphey and colleagues have previously shown that a similar auto-regulated tTA gene is lethal to female fruit flies raised without tetracycline (inhibits tTA). Transgenic NWS, Lucilia cuprina and Drosophila melanogaster lines have been made carrying the female-lethal gene cassettes and are currently being bred to homozygosity. Various characteristics of the lines (e.g. female viability, fecundity, longevity, male competitiveness) will be investigated.

Genetics, Genomics and Evolutionary Entomology

A transgene-based maternally-driven RNAi system produces male-only progeny in the Mediterranean fruit fly, *Ceratitis capitata*

Giuseppe Saccone[1], Marco Salvemini[2], Valeria Petrella[3], Rocco D'Amato[4], Catello Lino Polito[5]

[1]University Federico II of Naples, Italy, [2]University Federico II of Naples, Italy, Italy, [3]University Federico II of Naples, Italy, [4]University Federico II of Naples, Italy, [5]University Federico II of Naples, Italy, Italy

In Ceratitis capitata, female sex is determined by Cctransformer (Cctra), which engages during XX embryogenesis a positive feedback loop by maternally provided CcTRA and secures the continuous production of CcTRA in XX developing individuals. In Ceratitis XY embryos, a Y-linked M factor promotes, either directly or indirectly, the inclusion of additional sequences into the Cctra mRNAs which contain in-frame stop codons that truncate the CcTRA ORF, causing the XY embryos to develop into adult males. Likewise, transgene in vivo silencing of Cctra by RNAi causes a breakdown of the positive feedback loop in XX embryos leading them to develop as fertile XX males. One of our a dozen transgenic lines line displayed an unexpected maternal effect. Transgenic females crossed with non transgenic males give rise to male-only XX and XY progeny irrespective of whether they carry the transgene. The observation that Cctra is functionally switched OFF even in non-transgenic XX siblings, suggests a maternal effect of the transgene. In the transgenic mothers RNAi could deplete eggs of maternal CcTRA protein that is required for zygotic activation of Cctra or maternally transmitted dsRNA molecules may be responsible for repressing early activation of zygotic Cctra. To further investigate the molecular nature of this maternal effect we are currently examining the genomic sequences surrounding the insertion site, which possibly drive transgene-expression in the female germ line. These findings may help to design a repressible transgene-based maternally-driven RNAi system which can be used as a novel sexing strategy to produce male-only progeny for SIT.

Transgenic approach in the genetic control of Lepidopteran insects, *Bombyx mori* and *Ostrinia furnacalis*

Anjiang Tan[1], Baolong Niu[2], Guoliang Fu[3], Luke Alphey[4], Zhiqi Meng[5], Yongping Huang[6]

[1]Shanghai Institute of Plant Physiology and Ecology, CAS, China, [2]Zhejiang Academy of Agricultural Sciences, China, [3]Oxitec. LTD., United Kingdom, [4]Oxitec. LTD., United Kingdom, [5]Zhejiang Academy of Agricultural Sciences, China, [6]Shanghai Institute of Plant Physiology and Ecology, CAS, China

The sterile insect technique (SIT) is an environmentally friendly, species-specific genetic control method, which largely depends on advancement of the insect transgenic technique. SIT or RIDL (release of insects carrying a dominant lethal) has been applied successfully in pest management such as the Mediterranean fruit fly, Ceratitis capitata and the yellow fever mosquito Aedes aegypti. However, there is seldom report about the genetic control of Lepidopteran insects which contains large amounts of pests and insects with economic importance. Here we present two different strategies in the genetic control of two Lepidopteran insects, the silkworm Bombyx mori and the Asian corn borer Ostrinia furnacalis. In B. mori, a male-only rearing technique used sex-specific alternative splicing has been established and showed female-specific lethality during the early larval stage. In O. furnacalis, a different strategy based on the sex chromosome-linked gene manipulation technique is undergoing to induce sex-linked lethality. A stable transgenic line of O. furnacalis has been established and this will shed light on the future genetic control of O. furnacalis.

Genetics, Genomics and Evolutionary Entomology

First and second generation paratransgenesis for control of vector-borne diseases

Ravi Durvasula
University of New Mexico School of Medicine, U.S.A.

Despite great advances in public health, insect-transmitted infectious diseases remain a leading cause of morbidity and mortality. Currently, the best methods for control of insect-borne diseases involve the use of chemical pesticides. Such campaigns may yield spectacular results, yet longterm efficacy remains a problem. Environmental toxicity, adverse effects on human health,emergence of insect resistance and the prohibitive cost limit the use of many pesticides.Therefore, the elimination of insect pests is neither practical nor probable. Evolving methods for control of vector-borne diseases rely on modification of insects. Paratransgenesis is a "Trojan Horse" approach to control of disease transmission. It employs the interactions between diseasetransmitting vectors, bacterial commensals of the vectors and transmitted pathogens. Commensal bacteria are isolated and genetically transformed in vitro to export molecules that interfere with pathogen transmission. The genetically altered bacetria are introduced into the host vector where expression of engineered molecules affects the host's ability to transmit the pathogen. This approach attempts to decrease pathogen transmission and employs, as a gene delivery mechanism, bacterial flora native to the host vector. The model system for paratransgenic control involves the vectors of Chagas disease, a disease of Central and South America. Paratransgenic methods are under development for control of sand fly-mediated leishmaniasis and Pierce's Disease, an agricultural disease of grapes and citrus crops that is transmitted by Glassy Winged Sharpshooters. Finally, second generation paratransgenic systems are under development that employ advanced nano-materials to achieve better targeting of recombinant molecules with minimal environmental impact of transgene release. This session will

Paratransgenesis to control the transmission of malaria

David Lampe[1], Nicholas Bongio[2], Sibao Wang[3], Marcelo Jacobs-Lorena[4]

[1]Duquesne University, U.S.A., [2]Duquesne University, U.S.A., [3]Johns Hopkins University, U.S.A., [4]Johns Hopkins University, U.S.A.

Malaria is a devastating disease that infects about 500 million people a year and kills between 1 and 2 million, mostly African children. About half the human population is at risk of infection. Additional strategies to complement vector control by insecticides and parasite control by drugs are urgently needed. One such alternative is paratransgenesis, the indirect alteration of the phenotype of the vector by the introduction of transgenic microorganisms into the midgut lumen. The E. coli hemolysin A secretion system was used in the mosquito symbiotic bacterial species, Pantoea agglomerans, to deliver a variety of anti-Plasmodium effector proteins in Anopheles sp. Engineered strains of P. agglomerans were able to inhibit the development of Plasmodium falciparum (a human parasite) and P. berghei (a rodent parasite) by up to 98%. Importantly, the fraction of mosquitoes carrying any oocysts at all (=prevalence) was decreased by up to 84%. We will also discuss efforts to move this system into other bacterial symbionts like Asaia sp. which are reported to colonize other mosquito tissues and display vertical transmission within mosquito populations. This work provides the basis for the use of paratransgenesis to complement other strategies to reduce the burden of malaria on human populations.

Panarthropod phylogeny based on mitochondrial genomes

Ui Wook Hwang[1], Shi Hyun Ryu[2], Eun Hwa Choi[3], Keum Hee Jang[4]

[1]Kyungpook National University, Republic of Korea, [2]Kyungpook National University, Republic of Korea, [3]Kyungpook National University, Republic of Korea, [4]Kyungpook National University, Republic of Korea

The phylogenetic positions of the phylum Tardigrada and the class Pycnogonida (Euarthropoda, Chelicerata) have been considered one of the most controversial issues in metazoan phylogeny. Up to date, the controversies still remain unclear although a variety of molecular data such as EST, mitochondrial genomes, and hox genes have been adopted for resolving the enigmatic problems. Here, we have done intensive phylogenetic analyses based on mitochondrial genomes of 4 tardigrades including the two new ones, a eutardigrade Pseudobiotus spinifer and a heterotardigrade Batillipes longispinosus, and 7 pycnogonids recently published. The gene arrangements of P. spinifer and B. longispinosus are identical to that of Limulus polyphemus except for the placement of tRNAIle (I) between tRNALeu(CUN) (L1) and tRNALeu(UUR) (L2) and peculiar placement of control region (CR). The present mitochondrial proteome phylogeny joins Tardigrada and Pycnogonida with Acariformes within Chelicerata sensu lato. Tardigrada, Pycnogonida, and Acariformes may have a minute rudimentary abdomen, a stylet or stylet-like mouthpart for piercing, and loss of a respiratory organ (except for some mites). Such types of morphological characters may arise with the evolution of microscopic body size and/or aquatic life. It implies that aquatic lives shown in water bears, sea spiders, and water mites may result from one or more aquatic invasion event(s) of certain terrestrial arachnids. Unjointed legs in tardigrades might be gained through secondary loss from jointed legs during the adaptive evolution of a certain terrestrial chelicerate in aquatic environment.

Genetics, Genomics and Evolutionary Entomology

Structure, evolution and phylogeny of polyneopteran mitogenomes

Shuichiro Tomita[1], Natuo Komoto[2], Kenji Yukuhiro[3]

[1]National Institute of Agrobiological Sciences, Japan, [2]National Institute of Agrobiological Sciences, Japan, [3]National Institute of Agrobiological Sciences, Japan

Polyneoptera is an assemblage of 11 insect orders consisting of lower neopteran insects. The interordinal relationships within Polyneoptera remain highly controversial and ancient rapid radiations are thought to be responsible. Only the monophyly of Dictyoptera and the sister relationship of Grylloblattodea and Mantophasmatodea have been repeatedly recovered by various molecular and morphological studies. Phasmatodea, whose phylogenetic position among Polyneoptera is quite unstable, has been thought to be a key taxon to resolve the polyneopteran phylogeny. Embioptera is the preferred candidate of the sister group of Phasmatodea but the lack of sequenced mitochondrial genome from this order prevented the molecular phylogenetic analysis based on mitogenome. We have determined the almost complete mitochondrial DNA (mtDNA) sequence of an Embioptera species (Aposthonia japonica) and explored the phylogeny of polyneopteran insects using nearly complete mitogenome sequences. Our analyses recovered a close relationship between Phasmatodea, Mantophasmatodea and Grylloblattodea. Dictyoptera was placed as a sister to this group. The monophyly of Orthoptera was confirmed and Plecoptera was placed as a sister group of this order. A. japonica was placed as sister to Verophasmatodea, a suborder of typical stick and leaf insects. There is a translocation of a large region including atp6, atp8, cox3, nad3, and nad5, as well as a duplication of the 12S rRNA gene.

Genetics, Genomics and Evolutionary Entomology

Phylogenomic, transcriptional and evolutionary studies of mitochondrial genomes for orthopteran insects

Yuan Huang
Shaanxi Normal University, China

The complete mitochondrial genomes of 50 species from Orthoptera were determined using primer walking with cloning sequencing strategy after Long PCR amplification. These mitochondrial genomes were comprehensively analyzed in properties with respects of gene content and rearrangement, base composition, codon usage, tRNAs and rRNA secondary structures, and structual domains in A+T-rich region. The phylogenetic relationships at taxonomic levels of subfamilies, families and superfamilies of Orthoptera were reconstructed based on complete mitochondrial genome data, from which we can obtain some important conclusions about the phylogentic relationships among major higher catogories of Orthoptera insects. Based on a robust phylogenetic tree, the evolutionary constraints of mitochondrial genome with respects of flying capacity (according to wing type) and ecotypes (according to habitats) were tested. The results shown that Ka/Ks is statistically significant different between longwinged and wingless insects, but no significant different among ecotypes. Finally, the mitochondrial genome transcriptional map of Oxya chinese were constructed based on the data from total RNA of larvae and adult samples through de novo transcriptome sequencing.

What can mitochondrial genomes tell about beetle evolution?: Strengths and pitfalls of mitochondrial phylogenomics

Hojun Song
University of Central Florida, U.S.A.

The ability to generate large molecular datasets for phylogenetic studies is a boon to biologists, but such expansion of data also introduces numerous analytical problems. Mitochondrial phylogenomics, the use of complete mitochondrial genomes (mtgenomes) in phylogenetics, provides a manageable platform for address various challenges in analyzing phylogenomic data. In this presentation, I discuss both strengths and pitfalls of analyzing mtgenome data in the context of the mitochondrial genome phylogeny of the insect order Coleoptera (Arthropoda: Insecta). Beetles comprise one of the largest radiations in the Tree of Life, containing more than 350,000 species, or approximately 25% of all described species. As a part of an NSF-funded Beetle Tree of Life Project, a large number of complete mtgenome sequences of major lineages within Coleoptera have been generated. I present the most comprehensive beetle mitochondrial phylogenomic study to date and discuss the resulting patterns, especially with respect to overcoming systematic bias in phylogenomic data.

Mitogenomics of the Coleoptera under dense taxon sampling

Alfried P. Vogler[1], Martijn J.T.N. Timmermans[2], Ladislav Bocak[3], Sujatha N. Kutty[4], Jun Lim[5], Ruie Nie[6]

[1]Natural History Museum, United Kingdom, [2]Natural History Museum, United Kingdom, [3]University of Olomouc, Czech Republic, [4]Natural History Museum, United Kingdom, [5]Imperial College London, United Kingdom, [6]Chinese Academy of Sciences, China

This study exploits next-generation sequencing technology for sampling of ~250 mitochondrial genomes from major lineages of the Coleoptera. The resulting tree resolves basal relationships with good support, and provides an increasingly reliable estimate of phylogenetic relationships within Coleoptera at the family level. We show that, if taxon sampling is sufficiently dense, full mitochondrial genomes are very strong markers in insect phylogenetics at the intra-ordinal level, despite the sometimes disappointing results of whole mitogenomes at inter-ordinal level and the difficulty of resolving deep relationships with individual mitochondrial genes. Yet, a few taxa show highly divergent mitogenomes, and cannot be placed reliably due to apparent long-branch attraction.

Mitochondrial genome evolution in Hymenoptera

Mark Dowton[1], Meng Mao[2], Andrew D Austin[3], Stephen Cameron[4], Norman F Johnson[5]

[1]University of Wollongong, Australia, [2]University of Wollongong, Australia, [3]The University of Adelaide, Australia, [4]Queensland University of Technology, Australia, [5]Ohio State University, U.S.A.

During the last 10 years, we have been investigating the utility of mitochondrial genome sequence data for investigating relationships within the highly diverse insect order Hymenoptera. We have been interested in two sources of phylogenetic information; (i) gene position and (ii) aligned DNA sequence data. However, prior to using gene position to infer phylogeny, we wished to establish whether gene position is selectively neutral, and whether all gene rearrangements are equally likely. We investigated the evolution of 67 tRNA mitochondrial gene rearrangements and found that gene position was generally selectively neutral. However, not all genes appear to be as mobile as others. For example, genes close to the AT-rich region are marginally more mobile than others, while some tRNA genes appear to move rarely. We also investigated the recovery of phylogeny using mitochondrial genome sequence data from 29 hymenopteran taxa, when aligned DNA sequences from each of the 13 protein-coding genes and 2 rRNA genes are analysed. We find that the Bayesian analysis of 1st and 2nd codon position nucleotide data to be superior than any other type of analysis. However, we consistently find that terminal branch lengths are very long relative to internal branch lengths. This suggests that a much higher level of taxonomic sampling is required than is currently available, if these data are to be used to address long-standing phylogenetic uncertainties in the Hymenoptera.

Phylogenetic position of Hesperiidae in Lepidoptera using mitochondrial genome data with the description of newly sequenced skippers

Iksoo Kim[1], Min Jee Kim[2], Ah Rha Wang[3], Jeong Sun Park[4]

[1]Chonnam National University, Republic of Korea, [2]Chonnam National University, Republic of Korea, [3]Chonnam National University, Republic of Korea, [4]Chonnam National University, Republic of Korea

Lepidoptera is one of the largest insect orders, but the phylogenetic relationships within this order, have yet to be adequately described. One of the unresolved relationships includes the monophyly of the Papilionoidea in relationship with the monotypic superfamily Hesperioidea. We present four new hesperid mitochondrial genomes (mitogenomes), representing three subfamilies: Pyrginae (Daimio tethys and Erynnis montanu), Coeliadinae (Choaspes benjaminii), and Heteropterinae (Carterocephalus silvicola). Along with the newly sequenced hesperid genomes phylogenetic analysis was conducted with all available lepidopteran mitogenomes, consisted of ~50 species in seven lepidopteran superfamilies. The test for the effect of optimization schemes (exclusion and inclusion of third codon position of 13 PCGs, 22 tRNAs, and two rRNAs, with and without partitions) also was performed. Currently, the datasets are under phylogenetic analysis, so resultant phylogenetic relationships of Lepidoptera including the position of Hesperiidae will be updated as further comprehensive analyses is completed.

Insect mitochondrial genome database (IMGD): An integrated platform for insect mitochondrial genomes

Wonhoon Lee
Graduate School of Agriculture, Hokkaido University, Japan

Mitochondrial genomes offer markers useful for understanding evolutionary relationships among insects. In 2009, the Insect Mitochondrial Genome Database (IMGD) was developed to support phylogenetic studies using insect mitochondrial genome sequences and comparison of genomic features across species. During the last three years, many researches have been conducted with the IMGD. Currently, the IMGD archive fully 255 sequenced mitochondrial genomes and 342,013 sequences in partially sequenced mitochondrial genomes from 74,896 hexapod species. In this database, through the species-driven user interface, users can quickly select and analyze mitochondrial genomes at any taxonomic levels with eight analysis functions. Moreover, species taxonomic analysis and distance matrix analysis recently introduced provides in-depth dissections. The IMGD has been a versatile informatics platform and will be maintained systematically for conducting systematic phylogenetic and comparative analyses of insects.

Regulation of transposons in pestiferous mosquitoes and tephritid fruit flies that are subjects of SIT programs

Peter Atkinson[1], Peter Arensburger[2], Robert H. Hice[3], Jennifer A. Wright[4]

[1]University of California, Riverside, U.S.A., [2]University of California, Riverside, U.S.A., [3]University of California, Riverside, U.S.A., [4]University of California, Riverside, U.S.A.

The genome-wide regulation of transposons in at least Drosophila melanogaster has been proposed to occur at least, in part, by small RNAs which, in a dicer-independent pathway. We were interested to determine if these piRNAs also exist in the mosquito Aedes aegypti and, if so, whether they are specific to the large and diverse transposon complement of this insect pest. We also sought to determine whether the expansion of genes involved in piRNA biogenesis in Aedes led to any of these genes having different stage and tissue specific expression relative to their orthologs in D. melanogaster. We find that while many piRNAs in Aedes are targeted to transposons, many also target protein-coding genes. We also find that some of the piRNA biogenesis genes of Ae. aegypti are expressed in somatic tissues. The implications of these findings will be discussed.

Transgenic sexing system for *Ceratitis capitata* (Diptera: Tephritidae) based on female-specific embryonic lethality

Ernst A. Wimmer[1], Christian Ejikeme Ogaugwu[2]
[1]*Georg-August-University Goettingen, Germany,* [2]*Georg-August-University Goettingen, Nigeria*

The Sterile Insect Technique (SIT) is more efficient and cost-effective when only sterile males are released. A female-specific lethality system based on a female-specifically spliced intron had been developed for transgenic sexing in theMediterranean fruit fly Ceratitis capitata to possibly overcome the fitness problems of classical genetic sexing strains. However, this transgenic sexing system showed lethality predominantly during the pupal stage. To create an early-acting lethality system, we combined the principle of this female-specific lethality system with an embryonic lethality system to yield an early-acting sex separation system. This female-specific embryonic lethality system makes use of a sex-specifically spliced intron that was artificially introduced into a hyperactive pro-apoptotic gene. The expression of this pro-papoptotic gene is driven by a conditional heterologous transactivator that is itself under the control of a blastoderm-specific promoter. Different transgenic combination strains showed varying strengths of female-specific embryonic lethality with some lines showing 100% female-lethality at embryonic stages while the lethality does not affect male flies which eclose at normal rates and behave regularly. Transgene modification by site-specific recombination in the sexing effector line was further performed and subsequent stabilization of the transgene by transposase-induced partial removal achieved to make this line safer for applications in operational SIT programs.

Transcriptional profiles of mating responsive genes from testes and male accessory glands of the Mediterranean fruit fly, *Ceratitis capitata*

Ludvik M. Gomulski[1], Francesca Scolari[2], Paolo Siciliano[3], Paolo Gabrieli[4], Marco Falchetto[5], Mose Manni[6], Anna R. Malacrida[7], Giuliano Gasperi[8]

[1]University of Pavia, Italy, [2]University of Pavia, Italy, [3]University of Pavia, Italy, [4]University of Pavia, Italy, [5]University of Pavia, Italy, [6]University of Pavia, Italy, [7]University of Pavia, Italy, [8]University of Pavia, Italy

Insect seminal fluid is a complex mixture of proteins, carbohydrates and lipids, produced in the male reproductive tract. This seminal fluid is transferred together with the spermatozoa during mating and induces post-mating responses in the female. Molecular characterization of seminal fluid proteins in the Mediterranean fruit fly, Ceratitis capitata, is limited, although studies suggest that some of these proteins are biologically active. We report on the functional annotation of 5914 high quality expressed sequence tags (ESTs) from the testes and male accessory glands, to identify transcripts encoding putative secreted peptides that might elicit post-mating responses in females. The ESTs were assembled into 3344 contigs, of which over 33% produced no hits against the nr database, and thus may represent novel medfly sequences. Extraction of the coding sequences resulted in a total of 3371 putative peptides. The annotated dataset is available as a hyperlinked spreadsheet. Four hundred peptides were identified with putative secretory activity, including odorant binding proteins, protease inhibitor domain-containing peptides, antigen 5 proteins, mucins, and immunity-related sequences. Quantitative RT-PCR-based expression analyses of a subset of putative secretory protein-encoding transcripts from accessory glands indicated changes after one or more copulations when compared to virgin males of the same age. Our results suggest that synthesis of the putative secreted proteins that play an active role in the seminal fluid may be transcriptionally regulated. This represents the first large-scale dataset for novel studies on functions and processes associated with the reproductive biology of Ceratitis capitata.

Female-specific embryonic lethality strains for the Mexican fruit fly, *Anastrepha ludens*

Marc F. Schetelig[1], Alfred M. Handler[2]
[1]*USDA, Agricultural Research Service, U.S.A.,* [2]*USDA, Agricultural Research Service, Gainesville, Florida, U.S.A.*

Transgenic strains were created for reproductive sterility and female-specific lethality to improve the biological control of tephritid fruit fly pests in the Anastrepha genus, based on a tetracycline-suppressible (Tet-Off) system to conditionally regulate the embryonic expression of a pro-apoptotic cell death gene. The Tet-off system consists of a driver cassette having the A. suspensa embryo-specific serendipity α gene promoter linked to a Tet-transactivator (tTA) used to drive expression of a phospho-mutated variant of the pro-apoptotic cell death gene, hid, from A. ludens. The AlhidAla2 variant was validated as having high cell death activity in in vitro A. suspensa cell death assays, that also determined the most efficient driver-lethal effector cassette combinations for use in Anastrepha transformants. This resulted in two hybrid transgenic A. suspensa strains exhibiting 100% lethality on tet-free diet, one being 96% lethal in embryos with no survival past the first larval instar, which is critical for pests that are most damaging in late larval stages. For female-specific lethality necessary for male-only strains, the Assryα-tTA embryonic driver strain was used with a new lethal effector strain (TREhs43-Cctral-AlhidAla2) having a medfly transformer intron placed in the 5' end of the AlhidAla2 lethal effector. The medfly tra intron is sex-specifically spliced, which removes translational stop codons from the female reading frame, and not the males, resulting in female-specific AlhidAla2 lethal expression. Creating driver-female-specific lethal effector hybrid strains in A. suspensa resulted in two strains having double-heterozygous transgene cassettes being 100% male-only, while four male-only strains were created having double-homozygous cassettes.

Assessment of genetic diversity of the olive fly Israeli SIT laboratory strain

Nikos E Zygouridis[1], Yael Argov[2], Esther E Nemny-Lavy[3], David Nestel[4], Kostas D Mathiopoulos[5]

[1]University of Thessaly, Greece, [2]Israel Cohen Institute for Biological Control, Israel, [3]Agricultural Research Organization, Volcani Center, Israel, [4]Agricultural Research Organization, Volcani Center, Israel, [5]University of Thessaly, Greece

Early attempts to apply the SIT on the olive fly, Bactrocera oleae, were unsuccessful, mainly due to the low competitiveness of the sterile mass-reared males compared to the wild ones. Recently, new efforts are underway in Israel to develop a vigorous and efficient mass-reared olive fly laboratory strain. In order to understand the genetics of the adaptation process and possibly link the corresponding loss of competitiveness to genetic markers, we followed the fluctuation of genotypic frequencies of ten microsatellite markers during the course of 22 generations of the colonization of a wild Israeli population in laboratory conditions. Effective and observed allele number is halved after 11 generations, so is mean heterozygocity. Practically, there is very little change between F0 and F1, there are substantial changes between F1 and F2-F5, and there is a virtual complete adaptation to the new laboratory environment by F11, since no more changes are observed between F11 and F22. If we assume that the loss of allele number and heterozygocity also reflects the loss of the "wild" character of the colonized strain and, possibly, the loss of a substantial part of its natural vigor, our results indicate that there is an apparent need to enrich a mass-reared colony at least every five to eight generations. Furthermore, simulation models indicated that while most of the observed frequency fluctuations were due to random drift, some alleles were probably under selection.

Towards the development of improved sterile insect release protocols: Genome analysis of three Australian tephritid pests

Stuart Gilchrist[1], Deborah Shearman[2], Marianne Frommer[3], Kathryn Raphael[4], William Sherwin[5], Nandan Deshpande[6], Marc Wilkins[7], John Sved[8]

[1]University of New South Wales, Australia, [2]University of New South Wales, Australia, [3]University of New South Wales, Australia, [4]University of New South Wales, Australia, [5]University of New South Wales, Australia, [6]University of New South Wales, Australia, [7]University of New South Wales, Australia, [8]University of New South Wales, Australia

We have sequenced the genome and transcriptome of three native Australian tephritids, including Bactrocera tryoni, the Queensland Fruit Fly, which is the major pest of horticulture in Australia and, increasingly, in the South Pacific. The other two species, B. neohumeralis and B. jarvisi, are also pests of agriculture in Northern Australia, but show different host fruit preference, dispersal ability, level of adaptation to laboratory and factory conditions, morphological differentiation and mating behaviour. Never-the-less, we are able to hybridise all three species in the laboratory. This will enable us to investigate the DNA correlates of important between-species differences. The B. tryoni genome has been sequenced to 60 times coverage and assembled with a current N50 of 16kb although many of the scaffolds are greater than 1Mb. The assembled scaffolds contain mainly unique sequences. Although partial, near-complete and complete sequences for several families of transposable elements are abundant, these generally do not interfere with assembly. The Maker annotation software predicted over 10,000 transcripts based on both the transcriptomic data and de novo predictions. Analysis of the data will identify the full range of transposable element families within each species. This will be of use in predicting the compatibility of new transposable element constructs for future transformation experiments. In addition, degraded elements can provide unique genetic species markers. Comparison of sex determination genes in all three species will allow RNAi constructs with conserved tra or tra-2 gene sequences to be developed for construction of male-only SIT strains.

Development and characterization of genetic sexing strains of the oriental fruit fly, *Bactrocera dorsalis*, and the guava fruit fly, *Bactrocera correcta* for SIT

Sujinda Thanaphum[1], Siriwan Isasawin[2], Nidchaya Aketarawong[3]

[1]Faculty of Science, Mahidol University, Thailand, [2]Faculty of Science, Mahidol University, Thailand, [3]Faculty of Science, Mahidol University, Thailand

The oriental fruit fly, Bactrocera dorsalis (Hendel), and the guava fruit fly, Bactrocera correcta (Bazzi), are key economic pests for commodity fruits in Asia and Pacific regions. Area-wide Integrated Pest Management programmes using Sterile Insect Technique have been implemented in order to suppress fruit fly populations in several pilot areas in Thailand. Sterile insect techniques (SIT) continues to reveal areas where new technologies can improve the effectiveness of fruit fly control. One SIT advancement concerns genetic improvement of insect strains. Two stable white pupae-based genetic sexing strains have been developed and maintained. They were B. dorsalis and B. correcta and named Salaya1 and Salaya2, respectively. Mass rearing and release conditions for the Salaya1 have been evaluated. A modular mass-rearing facility for the sexing strain has been constructed and used to produce flies for open field trial, resulting in suppression of the wild population and lower fruit infestation rate. Moreover, microsatellite DNA makers have been characterized, evaluated and applied to monitor the quality of the mass reared strain and used for strain identification. These markers have also been used to study re-mating in a field cage test.

Approaching problems for Anastrepha fraterculus SIT with genetic and molecular tools: reproductive strategy, sex determination, and loss of variability in the lab

Jorge Luis Cladera[1], Marianela Juri[2], Alejandra Parreno[3], Cecilia Giardini[4], Silvia Lanzavecchia[5]
[1]INTA, Argentina, [2]INTA, Argentina, Argentina, [3]INTA, Argentina, [4]INTA, Argentina, Argentina, [5]INTA, Argentina, Argentina

In South America Anastrepha fraterculus (Wiedemann) (Diptera: Tephritidae) is an important fruit pest, sharing habitat in some subtropical and temperate regions with Ceratitis capitata (Wiedemann). Both species cause economical losses on fruit producing areas, and limit their access to international markets due to quarantine restrictions imposed by the fruit-fly-free countries. Currently, only insecticides are used to reduce the density of wild populations of A. fraterculus, so the use of environmental friendly control strategies against this pest is strongly recommended. We are performing laboratory studies on the biology, behaviour and genetics of these two species focusing on helping to the integrated actions against this pest and providing useful information about rearing and genetics to the development of SIT technique. Recently we participated in the isolation and characterization of A. fraterculus microsatellite markers, an achievement that opened a wide door to the study of the genetic variability of wild populations of this pest and, to the knowledge of the biological and physiological changes suffered by these insects when they are introduced to artificial rearing, thus understanding the genetic processes underlying during the adaptation to laboratory conditions. Our initial results revealed that microsatellite markers both in laboratory and wild populations of A. fraterculus from Argentina are highly polymorphic for 15 markers analyzed so far, whereas other 10 markers are under evaluation. A number of studies are in progress in order to use this molecular tool to solve biological problems as reproductive strategy, sex determination, loss of variability in the lab.

A genetic sexing strain (GSS) has been developed for the Mexican fruit fly Anastrepha ludens based on a Y-autosome translocation system. In this GSS typically males emerge from brown (wild type) and females from black (mutant) pupae. Cytogenetic analysis of mitotic chromosomes of this strain showed a reciprocal translocation between the longest chromosome 2 and the Y chromosome. Polytene chromosome analyses showed significant ectopic pairing of chromosome element III and therefore suggest that this chromosome is involved in the translocation and therefore corresponds to chromosome 2 of the mitotic complement. This GSS strain has been named "Tapachula-7" and was scaled to semi-mass rearing in the operational Moscafrut Program. A filter rearing system is implemented to maintain the integrity of the strain. , i.e. each generation aberrant flies are removed from the mother stock according to their pupal colour phenotype. The egg hatch has been around 70%, which is a value higher than theoretically expected for a strain carrying a Y-autosome translocation. The evaluation of the fitness and genetic stability in a semi-mass rearing system has been carried out at densities of 3000 pairs of flies per cage each generation; quality control parameters were measured in order to establish reference parameters of the filter rearing system. The genetic studies of aberrant individuals (crosses with "black pupae" mutants and "wild type" flies) help us to identify possible events that could destroy the genetic sexing system.

Improving the sterile sperm ID method for its implementation in the aw-SIT program against *C. capitata* in Spain

Maria A Juan-Blasco[1], Pedro Castanera[2], Alberto Urbaneja[3], Beatriz Sabater Munoz[4]

[1]Instituto Valenciano de Investigaciones Agrarias (IVIA), Spain, [2]Centro de Investigaciones Biologicas (CIB), Consejo Superior de Investigaciones Cientificas (CSIC)., Spain, [3]Instituto Valenciano de Investigaciones Agrarias (IVIA), Spain, [4]Instituto Valenciano de Investigaciones Agrarias (IVIA), Spain

In area-wide SIT programs against Ceratitis capitata, the success of the released sterile males is regularly measured by indirect methods, considering that the SIT program works when the ratio is balanced to sterile males. However, this method does not take into account the real target of the SIT, which is the wild female. To fulfil this gap, a sperm ID method based on molecular sperm identification in trapped females was developed in 2007 for the Spanish medfly populations. This protocol required three working days to analyse only 30 samples, which made difficult its practical application for aw-SIT programs due to the high handling time and personnel cost. The objectives of this work were: 1) to check of the validity of the sperm ID method with medflies from different world regions, and 2) to improve it and adapt it to hightroughput techniques for its cost-effective application to aw-SIT programs. Firstly, we validatedthe developed PCR markers. All the tested wild populations lacked the HaeIII characteristic haplotype of the sterile male lines, rendering the markers universal for other regions. Secondly, by modification of the spermathecae extirpation procedure and their conservation protocol,we were able to reduce handling time and costs (more than 96 samples analysed per run). In addition, this new protocol is able to detect sterile sperm in preserved wild female's samples trapped under field conditions for more than 28 days. The implementation of this improved sperm ID method to an aw-SIT program as the one in course in Eastern Spain is discussed.

[1]Programa Moscamed Guatemala, Guatemala, [2]USDA-APHIS-PPQ/CPHST, c/o American Embassy- Guatemala City, Guatemala, [3]USDA APHIS PPQ CPHST, San Miguel Petapa Fruit Flies Mass Rearing, Guatemala, [4]Programa Moscamed Guatemala, Guatemala, [5]Programa Moscafrut ?DGSV SAGARPA, Mexico, [6]Programa Moscafrut -Depto. de Validacion, Mexico, [7]McInnis Consulting Services, Guatemala, [8]USDA APHIS PPQ CPHST Mission Lab, U.S.A., [9]APHIS-PPQ/CPHST, Guatemala

A genetic sexing strain (GSS) of the Mexican fruit fly, Anastrepha ludens, was developed in 2008 in Mexico and has been recently evaluated for potential use in SIT programs in Mexico and the USA. The pupal color strain,Tapachula-7, is based on a recessive black pupae color gene in which the wild-type normal allele for brown color is genetically linked to the male Y-chromosome by means of a Y-autosome chromosomal translocation. Female pupae, black in color, and male pupae, normal brown in color, can be separated using electronic sorting machines to produce large populations of virtually all-male pupae for release in the field. A population of the strain was moved to Guatemala's fruit fly facilities for further larger scale rearing, quality control testing, and field evaluation. Since November, 2011 a team of investigators from Mexico, Guatemala, and the USA has been carrying out a series of field studies comparing both the GSS and a standard bisexual strain against wild A. ludens, including: field cage mating competition and outdoor survival in Retalhuleu, Guatemala; induced pupal suppression in large field cages in Antigua, Guatemala; and fly dispersal and longevity in the open field in south Texas, USA. As of March, 2012, the GSS has been of superior quality compared to the standard bisexual strain and very competitive with wild flies. Barring an unforeseen problem in the final stages of field testing, the GSS should soon provide a high quality, improved replacement for the current bisexual strain of A. ludens in future SIT programs.

SIT programmes for population control of the codling moth, Cydia pomonella, are based on bisexual releases. Male-only releases have never been tested in the field due to the lack of efficient sexing method. We proposed to develop genetic sexing lines in this pest by inserting a selectable transgene (a dominant conditional lethal mutation) into the female-specific W chromosome. Under restrictive conditions the transgene would abort development of females and thus, non-transgenic male-only offspring would be produced for irradiation and release. For germ line transformation of the codling moth, we have prepared a new plasmid construct called RATom. The RATom is based on a piggy-Bac vector and contains a red fluorescence marker gene, tdTomato, a partial sequence of the codling moth ortholog of the Drosophila Notch gene (CpNotch), the 3xP3 promoter, and gypsy insulators. The truncated CpNotch is expected to enable the intracellular Notch function at room temperature, while blocking embryonic development of transformed insects at a lower temperature. Functionality of the construct was verified in transfected cells of the embryonic Bombyx mori cell line BM1. Currently, its function is examined using a USA-Gal4 system in Drosophila lines transformed with RATom-pUAST construct to optimize temperature for conditional lethality. We also started with transgenic experiments in the codling moth. Moreover, we constructed a gene-based physical map of the codling moth Z chromosome using BAC-FISH. The map revealed that the codling moth Z had evolved through a translocation of an autosome, corresponding to Bombyx chromosome 15, onto the ancestral Z chromosome.

Role of the Y chromosome in the *Ceratitis capitata* sex determination and reproduction.

Giuseppe Saccone[1], Marco Salvemini[2], Rocco D'Amato[3], Archana Tomar[4], Valeria Petrella[5], Silvia Ciolfi[6], Romano Dallai[7], Daniela Marchini[8], Gerald Franz[9], Javaregowda Nagaraju[10], Catello Lino Polito[11]

[1]University Federico II of Naples, Italy, [2]University Federico II of Naples, Italy, [3]University Federico II of Naples, Italy, [4]Centre for DNA Fingerprinting & Diagnostics, India, [5]University Federico II of Naples, Italy, Italy, [6]University of Siena, Italy, [7]University of Siena, Siena, Italy, [8]University of Siena, Italy, [9]International Atomic Energy Agency, Austria, [10]Centre for DNA Fingerprinting & Diagnostics, India, [11]University Federico II of Naples, Italy

In Ceratitis capitata the sex determination occurs very early during embryogenesis: a Y-linked M factor (still to be isolated) represses the expression of a key master epigenetic switch, transformer (Cctraep) which promotes female sex determination,. In XX embryos, Cctraep is ON, and positively autoregulates throughout development. Transient or in vivo RNAi repressing Cctraep leads to the production of XX and XY male flies. Interestingly, XX males are fertile, indicating the absence of relevant Y-linked fertility factors. XX males transfer efficiently GFP-marked sperms into females. In a small scale competitive mating experiments, wild type females did not show any preference toward wild type or XX males. The microscopic observations of female storage organs revealed motile sperm cells in almost all the females mated either with wild type or with XX males. Experiments to assess the morphology and the ultrastructure of the reproductive apparatus as well as the protein pattern of the accessory glands from XX males are in progress. Experimental release of XX transgenic males and XY wild type males in semi-field conditions are underway to assess their competitiveness and evaluate their potential applications in the Sterile Insect Technique programs. We approached the identification of the Y-linked M factor(s) by subtraction approaches: mRNA samples, extracted from XX-only embryos and from mixed XX-XY embryos, were analyzed by Illumina mRNAseq and in silico subtraction. The initial results have led to the identification of dozens of putative male-specific transcripts which are under experimental validation.

Towards identifying sex determination pathway genes in the silkworm *Bombyx mori* for their possible use in genetic sexing strategies

Javaregowda Nagaraju
Centre for DNA Fingerprinting and Diagnostics (CDFD), India

With the recent developments in genetic and molecular basis of sex determination mechanisms and insect transgenesis, precise genetic sexing tools are now available mostly in dipterans, and are beginning to be exploited in the control of agriculture insect pests and human disease vectors. Such studies are scanty in Lepidoptera which embraces a large number of pest species that inflict heavy crop damage. The silkworm, Bombyx mori, unlike hymenopterans and dipterans, has the female heterogamety (ZW), and W chromosome plays decisive role in the female sex determination. Bombyx mori doublesex (Bmdsx) gene is sex-specifically spliced to yield male-specific and female specific polypeptides. The female splicing of Bmdsx pre-mRNA represents the default mode. BmPSI (P-element somatic inhibitor) is shown to work along with BmIMP (Bombyx homolog of IGF-II mRNA binding protein) to promote male specific Bmdsx splicing by binding to Exon Splicing Silencer (ESS) of exon 4. Recently, we have discovered two CCCH-type and C2H2-type type zinc finger proteins-encoding genes that map to the minimal W chromosome region that is sufficient to confer the femaleness in the silkworm. The experimental evidence suggests that these zinc finger proteins have role in sex-specific Bmdsx splicing pattern. We have identified an additional protein Bmhrp 28 (B. mori heterogeneous nuclear ribonucleoprotein 28) binding to ESS being expressed in both the sexes and its role as splicing repressor is being elucidated. These studies have bearing on the ongoing efforts to develop genetic sexing strains in Lepidoptera on the lines of dipteran agriculture pests and human disease vectors.

Cross mobility of piggyBac-like elements

Min Wu[1], Guanghua Luo[2], Xiaofang Wang[3], Zhaojun Han[4]

[1]Nanjing Agricultural University, China, [2]Nanjing Agricultural University, China, [3]Nanjing Agricultural University, China, [4]Nanjing Agricultural University, China

PiggyBac-like elements (PLE) are widespread in variety of organisms, however, few of them are active or have an intact transposon structure. Fortunately, we isolated two new functional PLEs, AyPLE1.1 and AgoPLE1.1 from the noctuid species Agrotis ypsilon and the cotton aphid Aphis gossypii respectively. The cross-mobility assays between the active transposases (IFP2, AyPLE1.1 and AgoPLE1.1) and the transposon ITR sequences from HvPLE1.1、TcPLE1、AgoPLE1.1、Uribo2、BmPBLE04、BmPBLE07 and BmPBLE69 were studied. The results showed neither of the functional transposase could recognize ITR sequences from other resources but its own. The results indicated ITRs determined the specificity of a functional transposase of piggyBac transposons. Similar cross-mobility assays between the active transposases (IFP2, AyPLE1.1 and AgoPLE1.1) and the sub-IR sequences from IFP2, TcPLE1 and PgPLE were studied. The results showed each of the three functional transposase could recognize all the sub-IR sequence from IFP2, TcPLE1 or PgPLE, and made precise excision events. However, statistics analysis revealed that the number of precise excision events were severely affected by alternation of different sub-IR sequences. These results show the possibility to increase the transposition frequencies of piggyBac by using its optimal sub-IR. These preliminary results were obtained in the S2 cell cultures, further studies in vivo were still needed.

The role of apyrene sperm in the polyandrous swallowtail butterflies

Mamoru Watanabe
University of Tsukuba, Japan

Females of the swallowtail butterfly mate multiply throughout their life span. During each copulation, the male butterfly fills first a white gel, structures a spermatophore in the bursa copulatrix of the female, and then transfer sperm. Spermatophores collapse, and represent nutrients for the polyandrous females to increase their longevity as well as fecundity. On the other hand, a large spermatophore protects a male's reproductive investment by delaying female remating. Immediately after the completion of copulation, both types of sperm, eupyrene and apyrene sperm, are found in the spermatophore. The eupyrene sperm is still in bundle, and they are gradually released in the spermatophore. About 9,000 eupyrene and 265,000 apyrene spermatozoa are counted in a single copulation. Because apyrene sperm are not in bundle, apyrene sperm migrate from the spermatophore to the spermatheca earlier than eupyrene sperm. Accordingly, if females mated multiply, the time difference may avoid the mixing of sperm, due to constructing the barrier of apyrene sperm of the mated male. Therefore, the predominance of sperm from the last mating session occur not in the bursa copulatrix but in the spermatheca. Since the spermatheca remains constant in size during the female life span, however, the excess sperm migration may cause the spermatheca to overflow. The spermathecal gland leading from the distal end of spermatheca is used for gradually filling eupyrene spermatozoa of the previous male. Selected hypothesis on the role of apyrene sperm proposed will be examined in the viewpoint of sperm competition.

Evolution of ultrasonic courtship signals through sensory bias in moths

Ryo Nakano
NARO Institute of Fruit Tree Science, Japan

Animals have evolved sexually attractive signals for successful mating. One origin of sexual communication can be attributed to the perception of predator-related cues. However, the evolutionary processes by which a receiver's sensory bias toward predator cues is coopted as a mating signal have remained enigmatic because receivers do not respond sexually to predators. Ultrasonic communication used by some moths in mating is thought to originate from the detection of ultrasonic calls emitted by bat predators, although this has not been demonstrated experimentally. Male Asian corn borer moths Ostrinia furnacalis (Lepidoptera, Crambidae), produce a 'whispering ultrasound' that immobilizes females, allowing the male to copulate freely. Here, I show that the corn borer moth male-courtship ultrasound and the ultrasound produced by bats are perceived similarly by female corn borer moths and generate a 'freezing' response in both cases. Thus, male courtship-ultrasound takes advantage of the avoidance response, making copulation easy. In contrast, both sexes of toxic Japanese lichen moths Eilema japonica (Lepidoptera, Arctiidae) generate warning clicks against attacking bats, and these females use male courtship-ultrasound as a signal for mate-recognition rather than freezing. These results support the notion that seductive mating signals have evolved under sexual selection to exploit preference by receivers that do not originally confound mate cues with predator ones.

The presence of rivals reduces reproductive fitness of male moths

Jin Xu[1], Qiao Wang[2]
[1]*Massey University, New Zealand,* [2]*Massey University, New Zealand*

Increasing evidence shows that spermatogenesis is costly. Therefore, males should optimize the use of their sperm to maximize their reproductive outputs in the dynamic natural environment. However, experimental evidence on how males do this is largely lacking. Here we examine how a male in copulation responds to the presence of rivals or additional mates and how such response influences his lifetime reproductive fitness. The model animal used here is a polyandrous moth Ephestia kuehniella Zeller (Lepidoptera: Pyralidae) where a female receives more than enough sperm from a single mating. We show that when rival males are present around a copulating pair the male ejaculates more sperm to his mate but in long term he inseminates fewer females, sires fewer offspring and lives shorter. The opposite is the case when additional females are present during copulation. These findings suggest that males can adjust ejaculate size in response to the risk of sperm competition and opportunity for remating. When the risk of sperm competition is high, the male ejaculates more sperm to his mate probably because the relative number of competing sperm in a female from different males determines the outcome of their relative paternity. However, the elevated ejaculation expenditure shortens the male longevity and reduces the number of females he can inseminate, resulting in fewer offspring sired by him in his lifetime. When the risk of sperm competition is low and the opportunity to mate with more females is high, males save sperm to inseminate more mates and sire more offspring.

Comparative evidence that copulatory spermatophore guarding is associated with smaller nuptial gifts and modifications in the form and/or use of the male's cerci in bushcrickets.

Karim Vahed[1], James David Jensen Gilbert[2], Ludivina Barrientos Lozano[3], David B Weissman[4]

[1]University of Derby, United Kingdom, [2]University of Sydney, Australia, [3]Jefe de Division en ITCV, Ciudad Victoria y aldredores, Mexico, [4]California Academy of Science, U.S.A.

The optimal mating duration, and/or volume of ejaculate transferred per mating, is expected to differ between the sexes, with male optima often exceeding those of females. Male crickets and bushcrickets exhibit a range of behaviours, including nuptial feeding (the spermatophylax) and copulatory spermatophore guarding (CSG), that appear to function to deter the female from interfering with ejaculate transfer. The hypothesis that these traits are analogous in function predicts that, across taxa, relative spermatophylax size will be reduced in species with CSG. The aims of this study were to test this prediction and to examine qualitatively differences in the structure and use of the male's cerci (which are used to grasp the female) between species with and without CSG. Data on ejaculate mass, spermatophylax mass and the duration of copulation following spermatophore attachment were obtained for 40 species of Tettigoniid. As predicted, relative nuptial gift mass correlated negatively with the duration of CSG across species. Males of species with CSG showed modifications in the structure and/or the use of the males' cerci, apparently increasing their effectiveness as grasping devices. Such adaptations included: elongated cerci which encompass the end of the female's abdomen; cerci with an increased number of projections and cerci in which the cercal teeth puncture the female's cuticle. The distribution of CSG within the Tettigoniidae suggests that this behaviour has evolved independently several times within the family.

What's so interesting about spider sperm?

Marie E Herberstein
Macquarie University, Australia

Most models of sperm competition assume mobile sperm that can actively compete with each other over fertilisation. Spider sperm offer a very different perspective as sperm tails are rolled up during transfer and require activation within the female sperm storage organ to gain mobility for fertilisation. This scenario places unique selective pressures on sperm evolution and opportunities for female control. In this presentation I will unveil the impressive, but possibly underestimated potential that spiders offer in the field of sexual selection and sperm competition.

Should inbreeding avoid or tolerate? Inbreeding avoidance or tolerance? Comparison of mating behavior between strong- and weak- inbreeding depression strains of the sweet potato weevil

Takashi Kuriwada
National Agriculture and Food Research Organizaion, Japan

Inbreeding depression is the decline of fitness as a result of mating with kin individuals. When inbreeding depression occurs, mating with a close relative is often considered maladaptive. However, in some situations, breeding with close relatives can provide inclusive fitness benefits and the benefits outweigh the cost of inbreeding. The sweet potato weevil Cylas formicarius has been mass reared over 74 generations using the sterile insect technique. Strains of the weevil exhibit varying extents of inbreeding depression (strong inbreeding depression: s-strain; and weak inbreeding depression: w-strain). Theory predicts that s-strain weevils will avoid inbreeding and w-strain weevils will tolerate inbreeding. To examine this prediction, we compared the effect of relatedness on the mating success of the two strains. Close-relative pairs of the w-strain copulated less frequently than non-kin pairs, but almost all s-strain pairs copulated — irrespective of relatedness. These results showed that the strain with weak inbreeding depression avoided inbreeding, and strain with strong inbreeding depression tolerated inbreeding. The contradiction between the theoretical prediction and our results is discussed from mating system and life history of the sweet potato weevil.

Nuptial feeding diversity and its morphological basis in scorpionflies (Mecoptera: Panorpidae)

Wen Zhong[1], Baozhen Hua[2]
[1]Northwest A & F University, China, [2]Northwest A & F University, China

Scorpionflies have interesting courtship and copulatory behaviors of nuptial feeding, which have been confirmed to have a morphological basis. The males with short notal organ have developed salivary glands. During courtship the male secretes a salivary secretion(s) as nuptial gift. Males of Neopanorpa longiprocessa have a well-developed notal organ, but have simple salivary glands and do not secrete salivary masses. The male usually uses his notal organ to hold the female for 1?2 h without nuptial gifts, likely a forced copulation. Males of Panorpa liui have complex clamp-like notal organ and undeveloped salivary glands, only providing dead insect as nuptial gift, without salivary masses. Males of Dicerapanorpa magna "dance" while disseminating sex pheromone. After a female is attracted to nearby, short-period copulation (20?60 min) was observed without nuptial feeding; then the male secretes a salivary mass, which is consumed by the female during long period of copulation (1?3 h). The male sometimes offers additional salivary secretions to prolong copulation. After the salivary secretion(s) has been consumed out, the copulation often elongate to extra 34?90 min without feeding. To sum up, remarkable diversity of courtship and copulation behaviors of scorpionflies is intimately correlated with their notal organs and salivary glands. Developed notal organ is associated with simple salivary glands, and vice versa. Nuptial gifts reduce sexual conflict by increasing paternity investment and supplying nutrients to females. This finding may play a role in the study of behaviour evolution and phylogeny of Panorpidae.

Scramble competition and sperm competition in a sexually cannibalistic mantis

Gregory Ian Holwell
University of Auckland, New Zealand

In species where males do not actively fight for access to females, competition between males largely consists of a race to locate their mates (scramble competition) and to fertilise their eggs (sperm competition). Scramble competition polygyny is perhaps the most common mating system in insects, and yet the factors influencing its evolution are largely unstudied. The sexually cannibalistic praying mantis, Pseudomantis albofimbriata exhibits a polygynous mating system, and females are highly cannibalistic, consuming approximately 40% of males encountered. In this species, both scramble competition and sperm competition therefore interact with the cannibalistic nature of females to determine the optimal mating strategy for males. Here, I will describe some recent research on P. albofimbriata demonstrating (a) last-male sperm precedence and (b) greater attraction to unmated females. I also show that when males are kept under conditions of high perceived risk of competition, they (b) develop to maturity more slowly, and (d) transfer larger ejaculates. Together, these results show that different components of male competition can interact in intriguing ways to determine the strategies that males use to maximize reproductive success.

Sexual selection on *Toxotrypana curvicauda* Gerstaecker (Diptera: tephritidae)

Alfredo Jimenez-Perez[1], Rene Arzuffi[2], Nancy Salmeron-Muniz[3], Patricia Villa-Ayala[4], Lilia Salazar-Marcial[5], Norma Robledo[6]

[1]Centro de Desarrollo de Productos Bioticos, Mexico, [2]Centro de Desarrollo de Productos Bioticos, Mexico, [3]Centro de Desarrollo de Productos Bioticos, Mexico, [4]Centro de Desarrollo de Productos Bioticos, Mexico, [5]Centro de Desarrollo de Productos Bioticos, Mexico, [6]Centro de Desarrollo de Productos Bioticos, Mexico

The papaya fruit fly, Toxotrypana curvicauda (Diptera: Tephritidae) is important to Mexican economy and is distributed in America from Florida to South America. Its chemical ecology and some aspects of the biology and behavior were revised previously; however, most information regarding sexual selection is missing. Female age triggers courtship and mating. Only 6-d-old females or older were proceptive and receptive. In non-choice and double choice tests, male age was not relevant to achieve mating. Male repertory and courtship vigor were similar at all ages tested. In one-choice tests, males that had already achieved one mating showed a weaker courtship than virgin insects. Mated males (24 or 48 in advance) invested less time in courtship than virgins' even in presence of mated or virgin females. Courtship and mating patterns (orientation, approaching, corporal movements, contact and mating) had different frequency in virgin that in previously mated couples. In double-choice laboratory experiment, nor males or females selected its partner based on weight, however, males always selected virgin females for mating while females may mated indistinctly with virgin or mated males. Finally, male hierarchy defined the male achieving mating.

Male responses to sperm competition: Adaptation, or are males just paranoid?

Zenobia Lewis[1], Anne Lize[2], Rowan Doff[3], Eve Smaller[4], Greg Hurst[5]

[1]University of Liverpool, United Kingdom, [2]University of Liverpool, United Kingdom, [3]University of Liverpool, United Kingdom, [4]University of Liverpool, United Kingdom, [5]University of Liverpool, United Kingdom

Males in many taxa are known to exhibit behavioural plasticity in response to the perceived intensity of sperm competition This is reflected in the fruit fly Drosophila melanogaster by increased copulation duration following prior exposure to a rival. We tested the prediction that males do not adult their copulation effort in response to the presence of rivals in Drosophila species where there is little or no sperm competition. Contrary to expectations, male plasticity in copulation duration was found in all species, even those where females rarely remate. The only exception was Drosophila bifasciata - in this species males transfer a mating plug to females during copulation. Our results will be discussed in relation to the adaptive basis of plasticity in these species.

Intra-specific variation in the effect of male-derived substances on female mating behaviours in *Callosobruchus chinensis*

Takeshi Yamane
National Agriculture and Food Research Organization, Japan

I demonstrated the intra-specific variations of the effect of male seminal substances influencing female oviposition, longevity, and fecundity among strains of the adzuki bean beetle, Callosobruchus chinensis. Previously, the effect of male seminal substances that induced female oviposition and reduce female longevity was identified. In this study, I examined the differences in the effect of male substances and female response to based on female oviposition, longevity, and fecundity among four strains of the C. chinensis with different re-mating frequency (mC, 5.9%: jC-S, 8.8%: akC02, 29.8%: isC, 38.4%). With respect to oviposition and longevity, the effect of male substances, female response to them, and interaction between male and female among strains were affected. Thus, female strains did not respond consistently to male substances from male strains extracted. Furthermore, female fecundity was also affected the effect of male substances, female response to them, and interaction between male and female among strains. These results indicate the variation and the possibility of evolutionary interaction of reproductive traits that affect reproductive success between both sexes.

Post-blood feeding changes in the transcriptomes of vector mosquitoes

Anthony A. James[1], W. Augustine Dunn[2], Osvaldo Marinotti[3], Xiaohui Xie[4]

[1]University of California, U.S.A., [2]University of California, U.S.A., [3]University of California, U.S.A., [4]University of California, U.S.A.

Hematophagy is a physiological trait ancestral to all extant mosquito lineages. We hypothesize that classes of genes were selected early in the evolution of mosquitoes to facilitate efficient blood-feeding and that orthologues of these genes are shared among modern mosquitoes. Furthermore, we propose that the mechanisms of transcriptional regulation of these genes may have been conserved along with the functional components and be reflected in conservation of cis-regulatory elements and modules (CREs and CRMs) in the control DNA. We are using transcriptomic analyses of genes expressed specifically in the midguts of four species, Aedes aegypti, Anopheles gambiae, Anopheles stephensi and Culex quinquefasciatus (Diptera: Culicidae), representing two subfamilies (Culicinae and Anophelinae) estimated to have diverged 145-200 million years ago, to identify and cluster genes. These data will leverage a combined comparative-genomics and expression-profile based CRE/CRM discovery strategy. The discovered CRMs will serve as the basis for validation of a set of conserved CREs that may be combined to drive robust anti-pathogen effector gene transcription in the midguts of vector mosquitoes directly following the ingestion of a bloodmeal.

The two-spotted spider mite Tetranychus urticae is an important crop pest and one of the most striking examples of polyphagy among arthropod herbivores. Recently the whole genome of this mite species was sequenced and reported. This genome is the first among chelicerates, and of great importance for general comparative phylogeny. It is also the first sequenced genome of a highly polyghagous crop pest and offers a unique opportunity to search for genomic and evolutionary signs of polyphagy and xenobiotic metabolism in arthropods. We annotated and studied known gene families implicated in detoxification, and found a species-specific proliferation of genes that might be related to remarkable ability of spider mites to survive on so many host plants. To investigate the role of these gene families in spider mite polyphagy, we used RNA-seq and microarray based transcriptome profiling of mites feeding on different hosts. We show that the expression patterns of mites feeding on different hosts are often correlated, defining a set of genes and gene families for further study. This genome-wide unbiased approach confirmed the important role of 'the usual suspects' in xenobiotic metabolism, but also uncovered several new gene families with a putative role in detoxification and stress response. We studied some of these gene families in detail, and reveal how they were acquired by horizontal transfer. Our results sheds new light on the remarkable adaptive potential of this crop pest and strongly argue that the xenobiotic metabolism of spider mites needs to be studied beyond classical detoxification genes.

Deconstruction of the plant primary cell wall: An insect perspective

Yannick Pauchet[1], Roy Kirsch[2], Heiko Vogel[3], David G. Heckel[4]

[1]Max Planck Institute for Chemical Ecology, Germany, [2]Max Planck Institute for Chemical Ecology, Germany, [3]Max Planck Institute for Chemical Ecology, Germany, [4]Max Planck Institute for Chemical Ecology, Germany

The primary plant cell wall is composed of an association between several polysaccharides, proteins and lignin. These polysaccharides include cellulose, hemicelluloses and pectins which represent the most abundant polysaccharides on the planet and a rich source of energy. Microorganisms, especially plant pathogens, are very efficient in utilizing these polysaccharides because their genomes possess genes encoding a range of enzymes able to degrade them. In contrast, the presence of such genes in higher eukaryotes is rare. The association between termites and their symbiotic protists is a text book example of cellulose digestion in insects, where not only the protists provide cellulose-degrading enzymes but also the insect itself. Recently, we demonstrated through transcriptome analyses, that the genomes of phytophagous beetles, especially species from the superfamilies Curculionoidea and Chrysomeloidea, possess diverse and large multi-gene families encoding a range of plant cell wall degrading enzymes (PCWDEs). To characterize these gene families and their respective function, we established an insect/plant model, the Mustard leaf beetle Phaedon cochleariae/Brassica rapa. I will present the results we got from the analysis of the larval gut lumen proteome of this beetle (I) to determine whether there are enzymes able to degrade plant primary cell wall polysaccharides and (II) to identify the proteins responsible for the enzymatic activities. We also compare the results obtained from this proteomics approach to those obtained from the analysis of the beetle transcriptome. I will also present a detailed functional characterization of one of the gene families that popped up after our combined proteomics/transcriptomics approach.

Molecular organization of *Drosophila* gustatory receptors in enteroendocrine cells

Jeong-Ho Park[1], Jae Young Kwon[2]
[1]*Sungkyunkwan University, Republic of Korea,* [2]*Sungkyunkwan Univ., Republic of Korea*

The gastrointestinal tract is emerging as a major site of chemosensation in mammalian studies. Enteroendocrine cells are chemosensory cells in the gut which produce regulatory peptides in response to luminal contents to regulate gut physiology, food intake, and glucose homeostasis, among other possible functions. Increasing evidence shows that mammalian taste receptors and taste signaling molecules are expressed in enteroendocrine cells in the gut. Invertebrate models such as Drosophila can provide a simple and genetically tractable system to study the chemosensory functions of enteroendocrine cells in vivo. To establish Drosophila enteroendocrine cells as a model for studying gut chemosensation, we used the GAL4/UAS system to examine the expression of all 68 Gustatory receptors (Grs) in the intestine. We find that 12 Gr-GAL4 drivers label subsets of enteroendocrine cells in the midgut, and examine colocalization of these drivers with the regulatory peptides neuropeptide F (NPF), locustatachykinin (LTK), and diuretic hormone 31 (DH31). RT-PCR analysis provides additional evidence for the presence of Gr transcripts in the gut. Our results suggest that the Drosophila Grs have chemosensory roles in the intestine to regulate physiological functions such as food uptake, nutrient absorption, or sugar homeostasis.

Midgut transcriptomics of an invasive insect species

Omprakash Mittapalli[1], Praveen Mamidala[2], Swapna Priya Rajarapu[3], Pierluigi Bonello[4], Daniel Herms[5]

[1]The Ohio State University/OARDC, U.S.A., [2]The Ohio State University/OARDC, U.S.A., [3]The Ohio State University/OARDC, U.S.A., [4]The Ohio State University/OARDC, U.S.A., [5]The Ohio State University/OARDC, U.S.A.

The insect midgut represents one of the major tissue interfaces that deal with several important physiological functions including digestion, detoxification and immune response. The emerald ash borer (Agrilus planipennis), is an exotic invasive insect pest that has killed millions of ash trees (Fraxinus spp.) primarily in the Midwestern United States and Ontario, Canada. However, despite its high impact status little knowledge exists for A. planipennis at the molecular level. An initial pass using Roche-454 pyrosequencing resulted in 25,173 high quality expressed sequence tags (ESTs) for larval A. planipennis midgut. A high number of the midgut sequences contained chitin-binding peritrophin (248) and trypsin (98) domains. Further, the midgut transcriptome of A. planipennis revealed putative microbial transcripts encoding for cell-wall degrading enzymes such as polygalacturonases and endoglucanases. A significant number of SNPs (137) and microsatellite loci (317) were also predicted in these sequences. qPCR quantification of cytochrome P450s belonging to various CYP clades revealed distinct expression patterns at the tissue level. On-going RNA-Seq experiments i.e. differential gene expression in A. planipennis larvae reared on resistant versus susceptible ash trees and small RNA profiling should provide new insights into the midgut physiology of this invasive insect pest. These findings will lay the foundation for future functional studies in A. planipennis and the results obtained will be essential both at the applied and basic scales.

Transcriptomic responses of the lepidopteran midgut to xenobiotics

Gaelle Le Goff[1], Meava Giraudo[2], Frederique Hilliou[3], Tran Trang[4], Rene Feyereisen[5]
[1]INRA, France, [2]INRA, France, [3]INRA, France, [4]INRA, France, [5]INRA, France

The fall armyworm Spodoptera frugiperda is a major pest of agriculture that is highly polyphagous, feeding on more than 25 host plant families. This phytophagous insect has thus developed sophisticated mechanisms to metabolically inactivate some of the potentially toxic xenobiotics that it encounters. To investigate patterns of gene induction in response to xenobiotics, we have contructed a Spodoptera frugiperda microarray consisting of 9773 60-mers oligonucleotides designed from EST libraries obtained from eight different tissues, developmental stages and treated insects. We addressed this array with cDNAs prepared from midguts of larvae fed with 5 plant allelochemicals, 4 insecticides and 2 model inducers, as well as from Sf9 cells treated with those compounds. We show that each chemical has a quite specific response, with few genes affected in common between all treatments. This implies that there are multiple transduction pathways interacting to provide the insect with an adapted response to its chemical environment. The response of Sf9 cells has little in common with the in vivo response of midgut tissue. We also studied by RT-PCR the response of various CYP genes to the eleven chemicals and will report on the catalytic activity of inducible P450s that are produced in a yeast heterologous system.

Genetics, Genomics and Evolutionary Entomology

CD36 family proteins are responsible for the tissue specific uptake of certain carotenoid species in the silkworm, *Bombyx mori*

Kozo Tsuchida[1], Takashi Sakudoh[2]

[1]*National Institute of Infectious Diseases, Japan,* [2]*National Institute of Infectious Diseases, Japan*

The silkworm, Bombyx mori provides very clear examples of tissue-specific delivery for certain carotenoid species from the midgut lumen to the silk gland via hemolymph lipoprotein, lipophorin. Lipophorin contains lutein and beta-carotene as a complex mixture of lipids in the hydrophobic core. The yellow (C) or flesh color cocoon (F) mutants accumulate lutein or beta-carotene in the middle silk gland from lipophorin, respectively. We have reported that the C gene encodes Cameo2, a member of CD36 gene family which has been known to function as as lutein specific transporter and transmembrane non-internalizing lipophorin receptor in the middle silk gland. The nature of the F gene was defined by positional cloning and transgenic rescue experiments with the binary GAL4-UAS expression system. The F gene encodes SCRB15, a paralog of Cameo2 with 26% amino acid identity. SCRB15 may be responsible for beta-carotene specific non-internalizing lipophorin receptor. In the F mutant, SCRB15 is not expressed because the mRNA structure of SCRB15 is severely disrupted due to a 1.4 kb insertion in a coding exon. This finding that both C and F genes encode CD36 homologs raises questions how CD36-homolog proteins recoginize the difference of carotenoid species which permits to uptake the middle silk gland from lipophorin.

Keywords:*CD36, carotenoid, lipophorin*

Physiological genomics of lepidopteran larval digestive lipases

John Tane Christeller[1], Sawsan Amara[2], Frederic Carriere[3]

[1]Plant and Food Research Institute, New Zealand, [2]Le Centre National de la Recherche Scientifique, France, [3]Le Centre National de la Recherche Scientifique, France

A major change in lipid quality occured with the evolution of autotrophy with galactolipids becoming the dominant source of long chain unsaturated fatty acids. Adapting to these novel lipids may have been yet another challenge in the evolution of phytophagy, in particular phyllophagy. Transciptome analysis of lepidopteran larvae midgut sequences identified lipases similar to GPLRP2, a vertebrate digestive enzyme with activity against galactolipids. We have measured galactolipase, phospholipase and triacylglycerol lipase activities in the midgut of six lepidopteran larval species, two folivores, two granivores, a carnivore and a keratinophage. The ratio of galactolipase to triacylglycerol lipase was high in the two folivores and low in the four other species, matching the major lipids in thier respective diets. In order to understand the evolution of galactolipase activity we have studied the exon-intron structure of insect digestive lipases and compared them with those from vertebrates of the same lipase superfamily.

Midgut enzymes from the spruce budworm: A genome-scale investigation

Daniel Doucet[1], Dayu Zhang[2], Michel Cusson[3], Roger Levesque[4]

[1]Natural Resources Canada, Canada, [2]University of Indiana, U.S.A., [3]Natural Resources Canada, Canada, [4]Universite Laval, Canada

Midgut enzymes are the frontline proteins involved in the conversion of insect food into insect biomass, and they have attracted significant interest for their potential as targets for insect control. While midgut enzymes can be characterized by directed protein or RNA sequencing from midgut tissue (proteomics, RNAseq, etc.), whole genome sequencing can provide a valuable complementary approach for the discovery of midgut enzymes. We are currently completing the sequencing and assembly of the genome of the spruce budworm (Choristoneura fumiferana) one of the most serious pest of fir and spruce in Canada. Genome sequencing was performed by a combination 454 GS FLX sequencing of BAC libraries and shotgun sequencing as well as GAIIx Illumina sequencing. Assembly has generated approximately 28 000 scaffolds covering 75% of the C. fumiferana genome. We will present results of the annotation of the major groups of digestive enzymes, e.g. peptidases, glucosidases, lipases and other proteins assisting in digestion. This genome-scale study will allow the characterization of unique patterns of digestive enzyme gene structure and function in a conifer-feeding Lepidoptera.

Networks: Small non-coding RNAs write the screenplay

Denis Tagu[1], Valentin Wucher[2], Jacques Nicolas[3]
[1]INRA, France, [2]INRA, France, [3]INRIA, France

The abstract concerns the introductive talk of the Symposium on "Small non-coding RNAs (sncRNAs) and genome expression". A huge amount of data is available for the description of sncRNAs in insect genomes as well as their role in regulating mRNAs or transposons. The sncRNAs usually act through physical interactions with their targets (mRNA, transposons) and the interactions may in some cases affect, reorient the fate of a phenotype. I will suggest the urgent need of federating approaches between entomologists and genomicists in one hand, and bioinformaticians and mathematical modelers in the other hand, in order to tackle from a pan-genomics perspective the whole regulatory networks required for biological adaption processes of insect to their environment and during their development. Examples will be taken from our studies on aphids and phenotypic plasticity. These networks are/will be a first step of a further integration of data, knowing that post-transcriptional regulation mediated by sncRNA is tightly linked to transcriptional (via transcription factors) and epigenetics (via chromatin modifications).

The role of microRNAs in host-pathogen interactions

Sassan Asgari
The University of Queensland, Australia

MicroRNAs (miRNAs) are small (~22 nucleotides) non-coding RNAs that play significant roles in various biological processes, including development, differentiation, apoptosis and immunity. In addition, pathogen or cellular encoded miRNAs play important roles in host-pathogen interactions by targeting the pathogen-encoded genes directly or by altering the expression of host genes that are beneficial to the pathogen. In turn, pathogens may manipulate their host miRNAs to facilitate their replication or enter into latency phase. Currently, there is little known about the role of miRNAs in insect host-pathogen interactions. Comparison of infected versus non-infected hosts using microarray or deep sequencing approaches provides valuable information with regard to identification of differentially expressed host miRNAs upon infection. In addition, pathogen-encoded miRNAs or small RNAs generated in host cells can be identified. We are using a number of host-pathogen systems to gain a better understanding of their role in the interactions. An overview of the latest outcomes in this area will be presented and discussed.

Non-coding RNAs in *Bombyx mori*

Yunchao Kan
Henan provincial key lab of Funiu mountain Insect Biology, China

Accumulating evidences show that small non-protein coding RNAs (ncRNAs) play important roles in development, stress response and other cellular processes. The silkworm is an important model for studies on insect genetics and control of lepidopterous pests. Here, we have performed the first systematic identification and analysis of intermediate size ncRNAs (50?500?nt) in the silkworm. We identified 189 novel ncRNAs, including 141 snoRNAs, six snRNAs, three tRNAs, one SRP and 38 unclassified ncRNAs. Forty ncRNAs showed significantly altered expression during silkworm development or across specific stage transitions. Genomic comparisons revealed that 123 of these ncRNAs are potentially silkworm-specific. Analysis of the genomic organization of the ncRNA loci showed that 32.62% of the novel snoRNA loci are intergenic, and that all the intronic snoRNAs follow the pattern of one-snoRNA-per-intron. Target site analysis predicted a total of 95 2′-O-methylation and pseudouridylation modification sites of rRNAs, snRNAs and tRNAs. We further employ Chip-Q-PCR to detect the functional role of some ncRNAs, and our results suggested that at least two ncRNAs act by engagement in epigenetic pathway. Together, these findings provide new clues for future functional study of ncRNA during insect development and evolution.

Gender and stressor specific microRNA expression in *Tribolium castaneum*

Andreas Vilcinskas[1], Dalial Freitak[2], Eileen Knorr[3], Heiko Vogel[4]

[1]Justus-Liebig-University of Giessen, Germany, [2]Justus-Liebig-University of Giessen, Germany, [3]Justus-Liebig-University of Giessen, Germany, [4]Max-Planck-Institute of Chemical Ecology, Jena, Germany, Germany

MicroRNAs (miRNAs) are small non-coding RNAs mediating post-transcriptional regulation of gene expression in eukaryotes. Addressing their role in regulation of physiological adaptations to environmental stress in insects we selected the red flour beetle Tribolium castaneum as a model. Beetles were fed with the bacterial entomopathogen Pseudomonas entomophila (to mimic natural infection), injected with peptidoglycan (experimental setting of strong immune responses) or subjected to either mild heat shock or starvation. Differential expression of selected immunity and stress-related genes was quantified using real-time PCR and expression and induction of 455 mature arthropod miRNAs was determined using proprietary microarrays. We found that Tribolium exhibits both gender- and stressor-specific adjustment of immune gene and miRNA expression. Strikingly, we discovered that the number of stressor induced miRNAs in females is remarkably higher than in males. This observation could support the hypothesis called Bateman´s principle in immunity that predicts gender specific immune responses because females gain fitness through increased longevity, whereas males gain fitness by increasing mating rates. Our results suggest that Tribolium males and females display differential regulatory elements, both pre- and post-transcriptional, likely resulting from different investment strategies in life history traits (Freitak et al. 2012: Biology Letters, in press).

The roles of miRNAs in metamorphosis development in *Chilo suppressalis* (Walker)

Sun Yang[1], Yu Lun[2], Zhang Zan[3], Li Fei[4]

[1]Nanjing Agricultural University, China, [2]Nanjing Agricultural University, China, [3]Nanjing Agricultural University, China, [4]Nanjing Agricultural University, China

To understand the roles of microRNA in the metamorphosis development, we first constructed small RNA library from four stages of rice stem borer, Chilo suppressalis. We obtained 57 conserved miRNAs by homology searching and 91 novel miRNAs by de novo identification. We tested all 148 miRNA using microarray in seven development points, ageing larvae (aL), prepupa (pP), early pupa (eP), compound eye (cE), pretarsus (pT), pupa elongation (Pe) and adults (Ad). As results, 76 miRNAs were successfully detected in these samples. Among which, 18 of them are differently expressed between seven tested-development stages. Two novel miRNAs, csu-1 and csu-2, show the highest expression at stage aL and cE, respectively. The csu-miR-277 showed about more than 10 times change between stage pP,cE and Ad, suggesting that csu-miR-277 play an important role in metamorphosis. Csu-miR-275a was highly expressed in pP, which may also participate in PCD and tissue lysis. Csu-miR-34 shows low expression change from pP to Pe. These results proved that microRNA have key roles in insect metamorphosis and might be used as the targets of pest control.

Genetic architecture of sexually selected traits in acoustic Lepidoptera

Michael D. Greenfield[1], Denis Limousin[2], Sylvain Alem[3], Rejane Streiff[4]

[1]CNRS Institut de recherche sur la biologie de l'insecte Universite Francois Rabelais de Tours, France, [2]CNRS; Universite Francois Rabelais de Tours, France, [3]CNRS; Universite Francois Rabelais de Tours, France, [4]INRA, UMR CBGP , France

Models sexual selection predict linkage disequilibria between genes influencing male traits and female preferences, owing to non-random mate choice or physical linkage. Such linkage disequilibria can accelerate the evolution of traits and preferences to exaggerated levels. Theory and empirical findings on species recognition suggest that such linkage disequilibria may result from physical linkage, but this possibility has seldom been addressed within the context of sexual selection. We studied the genetic architecture of sexually selected traits by analyzing signals and preferences in an acoustic moth, Achroia grisella, in which males attract females with a train of ultrasound pulses and females prefer loud songs and a fast pulse rhythm. Both male signal characters and female preferences are heritable traits. We employed a standard crossing design between inbred lines and used AFLP markers to build a linkage map for this species and locate quantitative trait loci (QTL) that influence male song and female preference. Our analyses revealed QTLs of moderate strength that influence various male signal and female receiver traits, and one QTL exerting a major influence on the pulse-pair rate of male song. However, we found no evidence of specific co-localization of QTLs influencing male signal and female receiver traits on the same linkage groups. This finding suggests that the sexual selection process would proceed at a modest rate in A. grisella and that evolution toward exaggerated character states may be tempered. We suggest that this equilibrium state may be more the norm than the exception among animal species.

Acoustic communication and dynamics of mating investments in bushcrickets (Orthoptera: Tettigoniidae)

Gerlind U.C. Lehmann
Humboldt University Berlin, Germany

Tettigoniid males signal their willingness to mate through their mating songs, which give females the opportunity to choose between different males without direct contact. The songs are assumed to communicate the male's quality and fitness. One of the males' qualities is the transfer of large nuptial gifts at mating. A male's fitness might be reflected in his investment in song production and spermatophore investment. The perceived assessment of mating opportunities on the one hand and the potential risk of competition by rival males on the other hand make male tettigoniid reproductive investments highly dynamic. I present data about the adjustment in males' song production and spermatophore investment patterns with regard to a range of environmental factors such as population density, male-male competition and a male's condition.

Behavioral plasticity and host specialization in an acoustically orienting parasitoid

David Gray
California State University, U.S.A.

Ormia ochracea (Diptera: Tachinidae) is a specialized acoustic parasitoid of Gryllus field crickets. Gravid female flies locate calling male crickets, and larviposit on or near the host. Here I review recent work on cricket acoustics and the potential trade-off between host specialization and evolutionary lability. This work includes molecular genetics, field playback experiments in single-host and multiple-host populations, as well as laboratory playbacks manipulating prior acoustic experience of the flies. I also briefly consider the impacts of specialized acoustic predators on the evolution of acoustic communication in crickets.

Age and the effect of social interaction on animal personality

Changseok Han[1], Robert Brooks[2]
[1]*The University of New South Wales, Australia,* [2]*The University of New South Wales, Australia*

Individuals in natural environment adjust their behaviour according to demographic factors. However, the longitudinal effects of social interactions on individual behaviour and behavioural syndromes have rarely been tested in animals. Here, male water striders (Hemiptera: Gerridae) were exposed to two different sets of conditions: the presence of only a single female (non-social treatment) or the presence of ten females and nine other males (social treatment). I then measured the consistency and plasticity of the following behaviours every two weeks over the lifetime of each male: dispersal ability, exploration in a novel environment, sex sensitivity (how quickly he recognized that another male is not a potential mate), and how long he persisted in attempting to mate a resistant female. All male personality traits except sex sensitivity varied consistently among males. Male dispersal tendency and exploratory behaviour remained more consistent over time in the social treatment than in the non-social treatment. Persistent mating attempts to resistant females were more consistent within the non-social treatment. In spite of behavioural consistency, males also varied in the plasticity of all behavioural traits. In particular, males from the social treatment become more likely to explore as they grew older, but the opposite was true of males from the non-social treatment. I conclude that the interaction between individuals contributes to the change of behavioural consistency and plasticity, potentially over the term of a male's life. Thus we suggest that demographic factors have an impact on the ecology and evolution of populations.

Reproductive isolation between two closely related cricket species, *Gryllus fultoni* and *G. vernalis*

Yikweon Jang
Ewha Womans University, Republic of Korea

Reproductive isolation between closely related taxa can occur via interruption of any stage of the reproductive process, prezygotic or postzygotic. However, a combination of several barriers is often required to eliminate costly reproductive interactions between closely related taxa. In eastern North America, two cricket species, Gryllus vernalis and G. fultoni (Orthoptera: Gryllidae), occur together in an area from eastern Kansas to northwest of the Appalachian Mountains. No hybrid offspring between two species were produced under laboratory conditions. Analyses of field and laboratory recordings showed that differences in pulse rate and chirp rate between the calling songs of the two species was greater in areas of sympatry than in areas of allopatry, a pattern expected of reproductive character displacement (RCD). The pattern of female mate discrimination in G. fultoni is also similar to the divergent pattern of calling songs between sympatric and far allopatric populations. At a common temperature, this female selectivity would be expected to significantly reduce heterospecific mating attempts in sympatry, consistent with predictions of RCD. Unlike those of G. fultoni, no comparable pattern of RCD is found in G. vernalis, resulting in asymmetry in RCD in this species pair. The final layer of premating reproductive isolation mechanism may be the discrimination by G. vernalis females against heterospecific males in close-range mating behaviors. Females of G. vernalis are selective with regard to mating, compared to those of G. fultoni. Thus, reproductive isolation occurs primarily in close-range mating behaviors in G. vernalis but in long-range mating behaviors in G. fultoni.

Understanding reproductive isolation in duetting green lacewings through the quantitative genetics of song and preference

Suegene Noh
Kansas State University, U.S.A.

Hybridization experiments can be used to estimate the genetic architectures underlying traits of interest as well as understand character homology of complex traits. Two cryptic species of green lacewings Chrysoperla agilis and C. carnea were crossed to identify inheritance patterns of species-specific mating signals and preferences for these signals. Multiple homologous genetic loci are hypothesized to underly both song features and preferences considering the recent origin of these species and the fact that these mating signals are the major reproductive isolation trait between the species. The inheritance of principal components describing hybrid song features fit additive (PC1), and additive plus dominance (PC2 & 3) models in joint scaling tests. Hybrids did not prefer the songs that most resembled the ones they themselves produced, and the variance in hybrid preference was greater than the variance in hybrid song features.

Plasticity of predator avoidance affect optimal timing of aposematic signaling in prey: Predictions from agent-based modelling

Woncheol Song[1], Piotr Grzegorz Jablonski[2], Sang-im Lee[3]

[1]Seoul National University, Republic of Korea, [2]Seoul National University, Republic of Korea, [3]Seoul National University, Republic of Korea

Warning sound to predators, or acoustic aposematism, can be evolved in several different ways in insects. Honeybees constantly emit buzzing sound, while certain moth caterpillars only click after an event of disturbance, and tiger moths utter ultrasonic warning at the final stage of bats' approaching behavior. An agent-based modeling technique was used to assess evolutionary prerequisites enabling each signaling strategy. The theoretical model newly predicted that if predator avoidance was learned rather than evolved, then preys tend to evolve a conditional or threat-based signaling strategy instead of more simplistic strategies. In addition, the model provided deeper understanding of evolutionary dynamics related to more conventional variables, including cost of signaling, predator learning speed and level of crypsis. Especially, level of crypsis was the strongest factor ruling signal conditions, unlike simple cost of signaling which mostly affected general strength of signaling only. These findings suggested that preys' investment to keep 'education' of predator population should be taken into consideration in predator-prey interaction studies, a step which has been widely neglected in previous studies.

Divergence in matingdisplays predicted by divergence in mate preferences, not their strength

Rafael L. Rodriguez[1], David Gray[2], Janette W. Boughman[3], Eileen A. Hebets[4], Gerlinde Hobel[5], Laurel B. Symes[6]

[1]University of Wisconsin-Milwaukee, U.S.A., [2]California State University, U.S.A., [3]Michigan State University, [4]University of Nebraska Lincoln, U.S.A., [5]University of Wisconsin-Milwaukee, U.S.A., [6]Dartmouth College, U.S.A.

After decades of intense research, the role of sexual selection in speciation remains unclear. We suggest that this ambiguity may be due to comparative tests of the effect of sexual selection on speciation not making a distinction between(i) the strength and(ii) the amount of divergence in the forces that causesexual selection. We address this distinction with taxonomically and methodologically diverse case studies of sexual selection via mate choice, including insects, spiders, frogs and fish. We relate quantitative descriptions of mate preferences to the distribution of sexual ornament traits, and find that ornament divergence is explained by the amount of divergence in mate preferences, rather than by their strength.This finding is intimately connected to speciation, because divergence in ornaments and mate preferences often directly influences assortative mating and reproductive isolation. We conclude that the effect of sexual selection on speciation may have been considerably underestimated to date.

The *Musca domestica* genome and transcriptome analysis in relation to insecticide resistance

Michael Kristensen[1], Jeff G Scott[2], Nannan Liu[3], Andrew G Clark[4]

[1]Aarhus University, Denmark, [2]Cornell University, U.S.A., [3]Auburn University, U.S.A., [4]Cornell University, U.S.A.

House flies are cosmopolitan, ubiquitous, and potentially transmit many human and animal diseases. The Musca genome will enable us to study the macro- and microevolutionary process of adaptation of the house fly to the changing agricultural and urban environment. The house fly has a well-described linkage map and genome size is < 2-fold larger than D. melanogaster. The house fly genome will expand our understanding of house fly biology and help in developing new control strategies and new insect control agents based on new targets or manipulation of the unusual autosome-based sex determination system. Insect immunity, sex-determination, insecticide resistance as well as comparative genomics of the host-parasitoid system Musca-Nasonia will strongly benefit from the housefly genome sequence. The house fly is one of the insect species that has shown a great ability to develop resistance to insecticides and has been followed in our lab from organchlorines to spinosad. Comparison of transcriptome (400.000 sequences averaging 250 bp) from insecticide-resistant and susceptible house fly strains revealed interesting difference in cytochrome P450 genes as well as other stress and toxicology related genes. The emergence of >30 insect genomes and an overwhelming amount of transcriptome data, now including the house fly genome and transcriptome data, during less than a decade will change insect research, as large amounts of data will rapidly become available. Studies of Musca ecology, physiology, pest control etc. will enter the genomic era. The benefits and the options of having the house fly genome at hand will be discussed.

Sex and the housefly: Evidence for a conserved bifurcation of the sex-determining pathway

Daniel Bopp[1], Nicole Meier[2]
[1]*University of Zurich, Switzerland,* [2]*University of Zurich, Switzerland*

The genetic pathway, which specifies neuronal functions and circuitries required for proper male courtship performance, has been extensively studied in Drosophila. In this insect model, the gene fruitless (fru), a direct target of the sex-determining cascade, has been identified as a key regulator of dimorphic development of the CNS. Little is known about the genetic control of sex-specific behaviours in other insects. We will present evidence that the fru ortholog in the housefly, Md-fru, is also required for proper male courting behaviour. Md-fru is a direct target of the sex-determining cascade in the housefly. Md-fru expresses functional products in male individuals in which the sex-determining switch gene transformer (Md-tra) is functionally OFF. Individuals, in which Md-tra is functionally ON, are instructed to develop into females and display no courting behaviour. Here, Md-tra causes a change in Md-fru splicing which leads to the incorporation of in-frame stop signals that render Md-fru functionally OFF. We characterized a mutant strain in which residual activity of a hypomorphic allele of Mdtra causes severely impaired courtship performance in homozygous males. While Md-dsx, the prime effector of the sex determining pathway is not affected by residual activity of Md-tra and is expressed in its proper male mode, Md-fru is spliced in the non-functional female mode. Removal of the residual Md-tra activity by RNAi shifts Md-fru back into its functional male mode of expression and reconstitutes normal male

The quest for the elusive male determining factors in the housefly

Leo W Beukeboom[1], Daniel Bopp[2]

[1]*University of Groningen, Netherlands,* [2]*University of Zurich, Switzerland*

The housefly is an exceptional organism in having populations with different sex determination mechanisms, including the standard male heterogametic (XX-XY) system, location of the dominant male determiner (M) on different autosomes, or female heterogamety. The frequency of autosomally located M factors shows worldwide clinal variation, being more abundant at higher temperatures. We will present approaches to identify the male determining gene(s) and to test theories about recombination suppression in neo-sex chromosomes. We will cross autosomal M strains to mutant laboratory strains to map, isolate and characterise M factors. We will exploit the Housefly Genome Project to develop dense marker linkage maps and identify candidate genes for functional analyses. We will measure local and genome wide recombination frequencies in strains with different sex determination mechanisms and establish temperature effects on sex determination gene expression (transcriptomics). We aim to gain a better understanding of the mechanisms and evolution of sex determination mechanisms in the housefly.

Age-dependent manifestation of sex-linked wings fragility mutation in *Musca domestica*

Galina Benkovskaya
Institute of biochemistry and genetics of Ufa Scientific Center of Russian Academy of Sciences, Russia

Identification of age-dependent changes of morphological deviations caused by mutations is an important experimental basis for investigations of genetic determination of aging and longevity. I present the description of new mutation causes the fragility of wings in house fly Musca domestica L. adults. Mutation "fragile wings" (fw) manifests in males only since 14-21 days after adults eclosion. Crosses between males with fragile wings and virgin females from original strain Cooper during 7 generations allowed to reveal the absence of fw phenotype in females. Female/male ratio in progenies is about 1:2. We proposed that mutation linked with X-chromosome and appears to be lethal for females when is homozygous. In laboratory house fly strains differing by life span (average life span of adults is 32-37 days in the strains Sh 28 and Sh gen, 47-52 days in strains L 2 and I gen) the significant share of males with fw phenotype was founded (0.25-0.55). This phenotype is expressed as the trait limited by sex. Further investigations required for elucidating the genetic basis of this trait. Investigations funded by Russian Foundation for Basic Research (grants 11-04-97005-r_povolzhye_a, 10-04-01614-a).

The transcriptome of hytrosavirus infected *Musca domestica*

Drion Garth Boucias
University of Florida, U.S.A.

Initially, the Roche's 454 GS-FLX system provided sequence on the Musca domestica hytrosavirus, a novel dsDNA virus that infect and sterilize various dipteran pest insects. Putative ORFs identified in the 125kbp MdSGHV were confirmed using both 3' RACE and qPCR. A second series of cDNA preparations were subjected to adaptor ligation, clonal hybridization to DNA capture beads and emPCR. Sequencing with the GS FLX titanium chemistry produced a total of 250,000 clean reads out of ~1x106 wells. The 37,449 assemblies were examined for contaminations (rRNA, mitochondrial reads) and the remainder annotated with NR blast hit, NT blast hit, Gene Title and GeneOntology terms. Analysis of the sequence data generated from the non-normalized library of cDNA revealed the presence of both housefly and MdSGHV transcripts. Quantitative analysis of the viral reads demonstrated the presence of abundant (18), moderate (29), and rare transcript classes (51). Interestingly, eight of the putative ORFs identified in silico were not detected in the sequences generated. After further filtering, a total of 37,449 assembled sequences were identified in the database of which 31,535 assemblies mapped to Drosophila homologues. Further annotation (housefly 454ASSEM_NR) revealed that of the 37,449 total, 14,590 queries had hits with e-values ≤ 0.0001; 9,352 with e-values between 0.0001 and 10, and 13,507 had no hits (e-values >10). The number of ESTs generated, although not as great as that generated from a normalized library, provided quantitative data on viral transcript abundance and a wealth of sequence data on house fly genes.

Opportunities and challenges of non-model ecoinformatics

Scott Emrich
University of Notre Dame, United States Minor Outlying Islands

Newer generation sequencing of co-occurring species with known ecology has transformative research potential and offers great opportunities for novel bioinformatics. Examples of such research include studying recent speciation, adaptation to climate change, and large-scale metagenomics in ecological settings. Here, we focus on analysis of co-occurring natural populations starting with our on-going and published transcriptome experience with two wild butterflies: the Propertius duskywing, \emph{Erynnis propertius} (Lepidoptera: Hesperiidae) and the Anise swallowtail, \emph{Papilio zelicaon} (Lepidoptera: Papilionidae). We compare and contrast these data with related restriction enzyme-associated sequencing (i.e., RADtaging) applied to genetic mapping and genome analysis of similarly sampled fruit flies (\emph{Rhagoletis} genus). We then describe opportunities and challenges of these datasets derived from two distinct newer generation sequencing platforms and their use in ecological informatics. This work is tied to our NIH/NIAID bioinformatics resource VectorBase that also is developing population genetics tools for vectors of human disease, All analysis is performed using our general and scalable framework that includes, among other tools, the discovery of SNPs, natural population haplotyping, and large-scale annotation of diverse environmental samples. We show runtime results of this framework using Amazon EC2, SGE, Condor and mixtures of the three. Finally, we share biological insights aided by our newer generation ecoinformatics including adaptation in malaria mosquitoes, differential responses to climate change of wild butterflies, and preliminary population genetics of field-caught Rhagoletis fruit flies. These applications involve model and non-model organisms and differences in the analysis will be discussed.

Analyzing biodiversity for bulk insect samples using Illumina NGS

Xin Zhou[1], Shanlin Liu[2], Yiyuan Li[3], Xu Su[4], Qing Yang[5], Ribei Fu[6]
[1]BGI, China, [2]BGI, China, [3]BGI, China, [4]BGI, China, [5]BGI, China, [6]BGI, China

Classic DNA barcoding protocols have been optimized for individual processing of biological samples. Next Generation Sequencing (NGS) technologies are considered as a potential solution to overcoming hurdles in data collection with accurate analysis of environmental samples of mixed taxa. Among current NGS platforms, Illumina sequencers have the potential to provide an efficient solution to analyzing environmental samples at much lower cost per sequence read. In this study, we first sequenced mixed amplicons for the standard barcode region obtained from insect samples collected by Malaise traps. Additionally, we developed a PCR?independent protocol to overcome taxonomic bias introduced by PCR amplifications.Our results show that the improved sequence length and the large sequencing capacity currently available on Illumina NGS has ensured its application to environmental biodiversity analysis, with several technical advantages: higher sensitivity for taxa with low abundance, higher recovery ratio for true positives, lower running cost per sample, and the capability to eliminate PCR bias. The application of Illumina platforms in bioassessment is promising, yet modifications of protocols in collection, preservation, and molecular lab work seem critical for this implementation.

Sex, Y genes and gene duplications in *Anopheles mosquitoes*: Integrating bioinformatics, next-gen sequencing, and digital droplet PCR

Zhijian Jake Tu
Virginia Tech, U.S.A.

The application of the so-called 2nd-generation sequencing technologies is having a profound impact on mosquito genetic research. Here I will first briefly discuss our efforts to obtain a draft Anopheles stephensi genome assembly by combining the 2nd-generation sequencing and a novel Focused Genome Sequencing approaches. I will then focus on a new strategy to integrate next-gen technology and bioinformatics to identify and characterize Y-chromosome genes and gene duplication events in Anopheles species.

Strain variation in the transcriptome of the dengue fever vector, *Aedes aegypti*

Anthony A. James[1], Mariangela Bonizzoni[2], W. Augustine Dunn[3], Corey L. Campbell[4], Osvaldo Marinotti[5], Ken E. Olson[6]
[1]University of California, U.S.A., [2]University of California, U.S.A., [3]University of California, U.S.A., [4]Colorado State University, U.S.A., [5]University of California, U.S.A., [6]Colorado State University, U.S.A.

Studies of whole-genome transcript modulation provide a basis for understanding functional elements of the genome and the complexity of gene regulation. Aedes aegypti, a significant vector of both dengue and yellow fever viruses, is adaptable to diverse ecological conditions and exhibits variation in vectorial capacity to arboviruses. Population genetic studies record a varying degree of world-wide genetic polymorphism, however, the extent of functional genetic polymorphism across strains was previously unknown. Transcriptomes of three Ae. aegypti strains, Chetumal (CTM), Rexville D-Puerto Rico (Rex-D) and Liverpool (LVP) were compared. CTM is more susceptible than Rex- D to infection by dengue virus serotype 2. Transcripts enriched in blood-fed mosquitoes encode proteins associated with catalytic activities, molecular transport, metabolism of lipids, carbohydrates and amino acids, and functions related to blood digestion and the progression of the gonotropic cycle. Significant qualitative and quantitative differences were found in individual transcripts among strains including differential representation of paralogous gene products. The majority of immunity-associated transcripts decreased in accumulation after a bloodmeal and the results are discussed in relation to the different susceptibility of CTM and Rex-D mosquitoes to DENV2 infection.

De-novo transcriptome sequencing to identify the molecular underpinnings of seasonal adaptation in the Asian tiger mosquito, *Aedes albopictus*

Peter Armbruster[1], Monica Poelchau[2], Christine Elsik[3], Julie Reynolds[4], David Denlinger[5]

[1]Georgetown University, U.S.A., [2]Georgetown University, U.S.A., [3]Georgetown University, U.S.A., [4]Ohio State University, U.S.A., [5]Ohio State University, U.S.A.

Many temperate insects survive the harsh conditions of winter by undergoing photoperiodic diapause, a pre-programmed developmental arrest initiated by short day lengths. To discover transcripts involved in diapause preparation, we sequenced and assembled the transcriptomes of Aedes albopictus early- (3 d post-oviposition) and late- (6 d post-oviposition) stage embryos reared under diapause-inducing or non-diapause-inducing conditions. Illumina Hi-Seq yielded ~120 million paired-end reads, which we combined with a previous assembly of 454-GS FLX reads derived from Ae. albopictus oocytes. Because an annotated genome sequence for Ae. albopictus is not currently available, we took advantage of strong sequence similarity to the genome sequence of Aedes aegypti, as well as other reference organisms, to annotate our assembly. We identified 12,293 ESTs with high-confidence annotations to known Dipteran gene models. Analyses of differential expression revealed strong ontogenetic changes in gene expression between early- and late- stage embryos in both diapause-destined and non-diapause destined embryos. While not as prevalent, gene expression differences between diapause-destined and non-diapause-destined embryos were present in both developmental stages, and were more pronounced later in development. Genes and pathways related to morphogenesis, metabolism and stress response were among the most strongly differentially expressed between diapause- and non-diapause-destined embryos in both developmental stages. Our analysis illustrates a useful approach that draws from closely related reference genomes to generate high-confidence ESTs in a non-model organism.

Genomic dissection of *Wolbachia*-dengue interactions in mosquitoes

Zhiyong Xi[1], Xiaoling Pan[2], Guoli Zhou[3], Jiahong Wu[4], Guowu Bian[5], Peng Lu[6], Alexander S. Raikhel[7]

[1]Michigan State University, U.S.A., [2]Michigan State University, U.S.A., [3]Michigan State University, U.S.A., [4]Michigan State University, U.S.A., [5]Michigan State University, U.S.A., [6]Michigan State University, U.S.A., [7]Michigan State University, U.S.A.

Diseases transmitted by blood-feeding arthropod vectors, such as mosquito-borne malaria and dengue fever, cause 1.5 million human deaths every year. The insufficiency of currently available strategies, including vaccines, drugs, and pesticides, has led to an increase in vector-borne diseases. The endosymbiotic bacterium Wolbachia is widely recognized for its potential as a vehicle to introduce disease-resistance genes into mosquitoes, making them refractory to the human pathogens they transmit. This is due to its ability to induce both a reproductive abnormality known as cytoplasmic incompatibility and a resistance to human pathogens including dengue virus (DENV) in mosquito. Here, we utilized several genomic tools to dissect molecular mechanism of this Wolbachia-mediated resistance to DENV. The microarray assay indicates that transcripts of genes with functions related to immunity and Redox are up-regulated in Ae. aegypti infected with Wolbachia. Infection with this bacterium leads to induction of oxidative stress and an increased level of reactive oxygen species (ROS) in its mosquito host. ROS elevation is linked to the activation of the Toll pathway, which is essential in mediating the expression of antioxidants to counterbalance the oxidative stress. This immune pathway is also responsible for activation of antimicrobial peptides (AMP), defensins and cecropins, which are involved in inhibition of DENV proliferation in Wolbachia-infected mosquitoes. Finally, three-way interactions between Wolbachia, DENV and mosquito will be analyzed in mosquito protein interaction network to further understand the mechanisms of viral interference. We will discuss the significance of our findings for development of novel strategies for control of vector-borne diseases.

Genomic analysis of inversion breakpoints revised the chromosomal phylogeny and evolutionary history of African malaria mosquitoes

Igor V Sharakhov[1], Maryam Kamali[2], Ai Xia[3], Zhijian Tu[4]
[1]Virginia Tech, U.S.A., [2]Virginia Tech, U.S.A., [3]Virginia Tech, U.S.A., [4]Virginia Tech, U.S.A.

Malaria mosquitoes often belong to complexes of morphologically indistinguishable sibling species that differ in geographic distribution, ecological adaptation, host-seeking behavior, and the ability to transmit a parasite. Understanding phylogenetic relationships within complexes is crucial for identifying the genomic changes associated with the evolution of epidemiologically important traits. To determine ancestral chromosomal arrangements in the An. gambiae complex, we identified breakpoints of fixed overlapping chromosomal inversions 2Rop of An. merus using fluorescence in situ hybridization, a whole-genome mate-paired sequencing, and clone sequencing. We also mapped breakpoints of a chromosomal inversion 2La in outgroup species using a bioinformatics approach. We demonstrated that the "standard" 2R+p arrangement and "inverted" 2Ro and 2La arrangements are present in three outgroup species, Anopheles stephensi, Aedes aegypti, and Culex quinquefasciatus. The data indicate that the ancestral species of the An. gambiae complex had the 2Ro+p and 2La chromosomal arrangements. The "inverted" 2Ro arrangement uniquely characterizes a malaria vector An. merus as the basal species in the complex. The rooted chromosomal phylogeny implies that the ancestral species gave rise to An. merus by generating the 2Rp inversion and to its sister species An. gambiae by generating the 2R+o inversion. We conclude that vectorial capacity had evolved repeatedly in the complex because it was lost in the intermediate An. quadriannulatus lineage and was originated again in the terminal An. arabiensis and An. melas lineages.

Genetics, Genomics and Evolutionary Entomology

Comparative genomics of insect pathogenic fungi

Qiang Gao[1], Peng Zheng[2], Guohua Xiao[3], Chengshu Wang[4]

[1]Shanghai Institutes for Biological Sciences, China, [2]Shanghai Institutes for Biological Sciences, China, [3]Shanghai Institutes for Biological Sciences, China, [4]Shanghai Institutes for Biological Sciences, China

There are about one thousand of known fungal species capable of killing insects. The species like Metarhizium anisopliae, M. robertsii, M. acridum and Beauveria bassiana has been developed as environmentally friendly biological control agents against different insect pests. The species of the caterpillar pupae specific fungus Cordyceps militaris, however, has been used a traditional Chinese Medicine for hundreds of years. We sequenced the genome of Metarhizium spp., B. bassiana and C. militaris to better understand the evolution of fungal entomopathogenicity and provide genetic resources to facilitate its exploitation. The insect pathogens have a strikingly larger proportion of genes encoding secreted proteins, particularly proteases, than other sequenced fungi. A phylogenomic analysis confirmed that entomopathogenicity is polyphyletic so similar expansion of families of proteases and chitinases reflects a convergent evolution. Nonetheless, the presence and absence of key virulence-related genes and the expansion and contraction of protein families in different insect pathogens suggest that fungi evolved diverse strategies to kill insects and or maintain host range. Like C. militaris, the sexualities of Metarhizium and Beauveria species are verified to be heterothallic. High throughput transcriptome analysis indicated that the pathogens could regulate transcriptional responses with fine-tuned gene sets for host recognition and adaptation to different niches. The information from our studies advanced the understanding of the evolution of fungal entomopathogenicity and will benefit future molecular studies of fungus-host interactions and thereby facilitate the development of vector pathogens as cost-effective environmentally friendly mycoinsecticides.

Genetics, Genomics and Evolutionary Entomology

Identifying microRNA genes from five important insect pests

Fei Li[1], Yun Lu[2], Yang Sun[3]

[1]Nanjing Agricultural University, China, [2]Nanjing Agricultural University, China, [3]Nanjing Agricultural University, China

Small RNAs are an important class of non-coding RNAs, including miRNA (microRNA), piRNA (piwi associated RNA), siRNA (small interfering RNA) and long non-coding RNA. In past decades, messenger RNA (mRNA) played major roles in molecular biology research because they encode proteins. Discovery of microRNA and piRNA opened a new era of noncoding RNA study . MicroRNA is one of the most important class of noncoding RNA genes, which involved in the growth of organisms, cell differentiation and apoptosis, tumor formation and occurrence of cancer and other life processes. Unfortunately, insect microRNAs has been less understood. In insect miRNA research filed, finding small RNA genes is still the important task. The traditional experimental methods is time-consuming and laborious. The deep sequencing technology provides a powerful tool to identify small RNA genes at a large-scale level. In this work, we sequenced small RNAs of five important agricultural pests, Tryporyza incertulas (walker), Spodoptera exigua Hiibner, Plutella xylostella(L.), Nilaparvata lugens(Stal), Laodelphgax striatellus. A comprehensive pipeline was developed to discover miRNAs by comparative genomics and machine learning methods. The genome of Bombyx mori and Acyrthosiphon pisum were used as the reference. As a result, 188 microRNAs were found, which has homoloies in the miRBase database. Fifty two microRNA were successfully identified by the software mireap using the reference genome. Combining transcriptome and small RNA library data, 41microRNA were successfully detected using miRDeep.

Genetics, Genomics and Evolutionary Entomology

Functional genomic analysis of chelicerate species

Xuan Li
Shanghai Institutes for Biological Sciences, China

Arthropoda comprises two major branches, Chelicerata and Mandibulata, which arose from Cambrian period and radiated into millions ofspecies over 400 millions of years. A comparative study was performed on transcriptome data from two arachnids, eleven insects, a crustacean, and two chordates. A phylogeny tree was built based on maximum likelihood analyses of orthologs in the eukaryotic core gene set. Chelicerates shared 3,806 gene families, and had 8,964 unique gene families. On the other hand, insects shared 676 gene families, and had 17,700 gene families specific to their own. Extending the analysis to include chelicerates, hexapods and crustacean, their common and unique genes highlight the genetic basis for many important biological features. The genetics repertoire of arthropods is likely the balanced outcome of gene accumulation and decay through a long history of evolution. This study offered insights into the evolution of chelicerates and arthropods.

Genome scale evolutionary analysis for revealing the oldest bacterial organism on the Earth

Yoshio Tateno
Pohang University of Science and Technology, Republic of Korea

We constructed a phylogenetic tree of 17 bacterial phyla covering eubacteria and archaea by using a new method and 102 carefully selected orthologs from their genomes. One of the serious disturbing factors in phylogeny construction is the existence of out-paralogs that cannot easily be found out and discarded. In our method, out-paralogs are detected and removed by constructing a phylogenetic tree of the genes in question and examining the clustered genes in the tree. We also developed a method for comparing two tree topologies or shapes, ComTree. Applying ComTree to the constructed tree we computed the relative number of orthologs that support a node of the tree. This number is called the Positive Ortholog Ratio (POR). Our result of bacterial phylogeny analysis is consistent with previous ones showing that hyperthermophilic bacteria such as Thermotogae and Aquificae diverged earlier than the others in the eubacterial phylogeny studied. It is noted that our results are consistent whether thermophilic archaea or mesophilic archaea is employed for determining the root of the tree. The earliest divergence of hyperthermophilic eubacteria is supported by genes involved in fundamental metabolic processes such as glycolysis, nucleotide and amino acid syntheses.

Bugs and drugs and speciation: The impact of mutualistic *Wolbachia* on *Drosophila* development, sexual behavior and symbiotic speciation

Wolfgang J Miller[1], Lee Ehrman[2], Daniela I Schneider[3]

[1]Medical University of Vienna, Austria, [2]Purchase College, State University of New York, U.S.A., [3]Medical University of Vienna, Austria

In speciation research it is still an ongoing debate over whether or not, and if yes to what extend, ubiquitous microbial reproductive tract symbionts have the ability of manipulating host sexual behavior in nature and - in their long-term consequence - of fostering biodiversity. We recently have reevaluated the role of native endosymbiotic bacteria Wolbachia on directing assortative mating in females as well as on pheromone expression and perception in both sexes in the neotropical Drosophila paulistorum species complex trapped mid-evolution in flagrant statu nascendi. Here we show that obligate mutualistic Wolbachia foster incipient host speciation by triggering both pre- and postmating isolation. As broadly accepted the actual formation of a new species is a slow process, generally requiring many generations, and therefore one cannot expect to artificially create vicariant speciation in the laboratory to yield substantial reproductive isolation. However, the D. paulistorum species complex presents an exceptional case providing compelling experimental evidence for any spontaneous creation of a new Drosophila species in the laboratory. As reported by DOBZHANSKY the D. paulistorum strain Llanos was originally compatible in crossings with Orinocan semispecies, but after five years in the laboratory this strain spontaneously had transformed into a new semispecies with complete hybrid male sterility. We have established artificial Wolbachia 'depletion-restoration' lines of D. paulistorum via antibiotics. Such lines consistently express strong de novo mate avoidance against parental untreated partners. Molecular and cellular mechanisms will be discussed triggering alterations in sexual behavior in response to artificial disturbances of the native host-symbiont equilibrium.

Genetics, Genomics and Evolutionary Entomology

Symbiont-mediated body colour change in aphids

Tsutomu Tsuchida
University of Toyama, Japan

In the pea aphid Acyrthosiphon pisum, red and green color morphs are found in the same populations. Early ecological studies showed that the color variation has some important traits, often involved in the prey-predation relationships. Recently we found an unexpected layer underlying aphid color polymorphism: novel aphid endosymbiont of the genus Rickettsiella is responsible for green body color in at least some green pea aphids in natural populations. Diagnostic PCR surveys in Western Europe, North America, and Japan revealed that prevalence of Rickettsiella was significantly different between those regions. Infection experiments of various Rickettsiella strains indicated that phenotypic effects of Rickettsiella infection on the body color were slightly different but they similarly changed the red body color into green. Aphid body color mainly consists of yellow-red carotenoid and blue-green polycyclic quinones. We could not find any significant changes of carotenoid compositions by HPLC and gene expression analyses. Meanwhile, TLC analysis suggested that Rickettsiella infection increased amounts of green polycyclic quinones and no new pigments appeared upon the Rickettsiella infection. We chemically characterized the main green pigments, and developed highly specific and sensitive detection method of the green pigments by using LC-MS. LC-MS analyses confirmed that both of Rickettsiella-infected and uninfected aphids contain same green pigments, although the amounts of the pigments were remarkably different between them. From those results, Rickettsiella probably does not synthesize the green pigments by itself but somehow interferes with the aphid metabolism to activate the green pigment production.

Invited submission (session 5-6 Advances in symbiosis, talk S6-4): Evolution of symbiont-mediated antibiotic defense in solitary wasps

Martin Kaltenpoth
Max Planck Institute for Chemical Ecology, Germany

Mutualistic microorganisms play a key role for nutrition or pathogen defense in many insects. Beewolves (digger wasps of the genera Philanthus, Trachypus and Philanthinus) engage in a unique symbiosis with Streptomyces bacteria that they cultivate in specialized glands in their antennae and transfer them to the larval cocoon. On the cocoon, the symbionts provide protection for the larva against fungal and bacterial pathogens by producing a complex cocktail of antibiotic substances. Thus, by means of their symbionts, beewolves employ a strategy comparable to the combination treatment used in human medicine as an efficient defense for their offspring against a broad range of detrimental microorganisms. We reconstructed multi-gene phylogenies for both symbiotic partners to elucidate the evolutionary history of this remarkable association. Molecular clock calibrations based on the fossil record of crabronid wasps indicate that the symbiosis evolved at least 65 million years ago. Thus, the association is more ancient than any other defensive insect-bacteria mutualism known to date. The beewolf symbionts form a monophyletic clade within the genus Streptomyces, suggesting a single infection event and subsequent co-diversification of hosts and symbionts. However, comparative phylogenetic analyses provide strong evidence for frequent horizontal transfer of symbionts, possibly by interspecific predation or nest re-use among beewolf species. Thus, defensive symbioses with extracellular bacteria can remain stable over long evolutionary timescales even in the absence of co-cladogenesis, demonstrating that strict vertical transmission is not a prerequisite for the maintenance of protective mutualisms.

Insecticide resistance governed by endosymbiontic bacteria

Yoshitomo Kikuchi[1], Masahito Hayatsu[2], Takahiro Hosokawa[3], Atsushi Nagayama[4], Kanako Tago[5], Takema Fukatsu[6]
[1]AIST, Japan, [2]NIAES, Japan, [3]AIST, Japan, [4]Okinawa Prefectural Agricultural Research Center, Japan, [5]NIAES, Japan, [6]AIST, Japan

Development of insecticide resistance has been a serious concern worldwide, where insecticide abuse results in evolutionary changes in the pest insect genomes such as alteration of drug target sites, up-regulation of degrading enzymes, enhancement of drug excretion, etc. Here we report a previously unknown mechanism of insecticide resistance: infection with insecticide-degrading bacterial symbiont immediately establishes insecticide resistance in pest insects. The bean bug Riptortus pedestris and allied stinkbugs are in mutualistic association with Burkholderia gut symbionts, which are acquired by nymphal insects from the soil environment. In agricultural fields, fenitrothion-degrading Burkolderia strains are present at very low densities. We demonstrated that the fenitrothion-degrading Burkholderia strains are able to establish a specific and beneficial symbiosis with the stinkbugs and confer a resistance of the host insects to fenitrothion. Experimental applications of fenitrothion to field soils drastically enriched fenitrothion-degrading bacteria from 0% to 80-90% of total culturable bacterial counts, and over 90% of stinkbugs reared with the enriched soil established symbiosis with the fenitrothion-degrading Burkholderia. In a Japanese island where fenitrothion has been regularly and constantly applied to sugarcane fields, we identified a stinkbug population wherein the insects live on sugarcane and around 8% of them host fenitrothion-degrading Burkholderia. Our finding may entail practical relevance in that the symbiont-mediated insecticide resistance can develop even in the absence of pest insects and quickly establish within a single insect generation.

Genetics, Genomics and Evolutionary Entomology

The role of the innate immune system of the ant *Camponotus floridanus* in regulation and maintenance of its endosymbiont *Blochmannia*

Heike Feldhaar[1], Carolin Ratzka[2], Roy Gross[3]

[1]*University of Bayreuth, Germany,* [2]*University of Wurzburg, Germany,* [3]*University of Wurzburg, Germany*

Numerous insect species harbour mutualistic endosymbiontic bacteria. Insect hosts face the problem of having to maintain such mutualistic bacteria while staging an immune response towards pathogens upon infection. Camponotus floridanus ants harbour the obligate endosymbiont Blochmannia floridanus in specialized midgut cells and ovaries. During the holometabolous life cycle of the ant hosts the distribution of bacteriocytes and of Blochmannia endosymbionts is remarkably dynamic. The proportion of cells of the midgut harbouring Blochmannia increases strongly during host ontogeny and peaks in late pupal stages, where the entire midgut is transformed into a symbiotic organ. After eclosion of workers the symbiosis degenerates as bacterial numbers decreases with age of workers. We identified genes transcriptionally induced in response to septic injury by suppression subtractive hybridization. Among these were genes involved in pathogen recognition, signal transduction, antimicrobial activity, or general stress response. A quantitative analysis of immune gene expression revealed different expression kinetics of individual factors and characteristic expression profiles after injection of gram-negative and gram-positive bacteria. B. floridanus injected into the hemocoel elicited a comparable immune response of its host C. floridanus. Furthermore, in untreated hosts some immune genes displayed distinct expression patterns according to developmental stage and tissue. Thus, the host´s immune system may prevent colonization of tissues other than the bacteriocytes by Blochmannia and may also play a role in the regulation of the number of bacteria present within bacteriocytes

Symbiont-mediated invasive success of the Harlequin ladybird *Harmonia axyridis*

Andreas Vilcinskas[1], Henrike Schmidtberg[2], Kilian Stoecker[3], Heiko Vogel[4]
[1]*Justus-Liebig-University of Giessen, Germany,* [2]*Fraunhofer Institute of Molecular Biology and Applied Ecology, Germany,*
[3]*Fraunhofer Institute of Molecular Biology and Applied Ecology, Germany,* [4]*Max-Planck-Institute of Chemical Ecology, Germany*

An increasing number of invasive species characterized by rapid growth and spread of populations after their establishment in new habitats impact negatively both biodiversity and economy. Their invasive success is promoted by several factors among which a strong immune system has been postulated because invaders have to cope with pathogens which they face in their new environments. We selected the harlequin ladybird Harmonia axyridis to explore the role of immunity in invasion biology. Its remarkable capacity to outcompete native ladybird species upon introduction into new habitats has been linked to its prominent resistance against pathogens. We discovered a strong constitutive antibacterial activity in the hemolymph of H. axyridis beetles which has been attributed to the chemical defense compound harmonine exhibiting a broad-spectrum activity against pathogens including those causing human diseases such as the infective agents of tuberculosis and malaria (Rohrich et al. 2012, Biology Letters). Surprisingly, injection of antibiotics decreased the antimicrobial activity in the hemolymph implicating the participation of symbionts in chemical defense of H. axyridis.

Prevalence of the symbiont *Cardinium* in *Culicoides* (Diptera: Certopogonidae) vector species.

Yuval Gottlieb[1], Neta Morag[2], Yonatan Saroya[3], Itamar Lensky[4], Eyal Klement[5]

[1]The Hebrew University of Jerusalem, Israel, [2]The Hebrew University of Jerusalem, Israel, [3]The Hebrew University of Jerusalem, Israel, [4]Bar-Ilan University, Israel, [5]The Hebrew University of Jerusalem, Israel

Infection prevalence of symbionts in arthropod hosts may vary according to several reasons among are the environmental conditions affecting the host. Here we identified and localized the symbiont 'Candidatus Cardinium hertigii' in two major livestock disease vector species of Culicoides biting midges (Diptera: Ceratopogonidae) from Israel, determined its geographic prevalence and its association with climatic factors. The prevalence of adult infection differed significantly between C. imicola and C. oxystoma, though phylogenetic analyses showed that Cardinium in these species are almost identical. The prevalence of infection differed significantly between climate regions with lowest prevalence in the arid region and highest prevalence in the Mediterranean region. In addition, multivariate linear regression analysis of Cardinium prevalence together with climatic and satellite imagery data-derived environmental variables revealed that infection prevalence is significantly and strongly associated with land surface temperature. These findings suggest that the observed variation of Cardinium infection of the imago stage of Culicoides species may be influenced by environmental conditions affecting the latter's early developmental stages.

Genetics, Genomics and Evolutionary Entomology

Repeated interactions and the evolution of dependence in insect symbiosis

Fabrice Vavre
Biometry and Evolutionary Biology Lab, France

Numerous insects interact with vertically transmitted symbionts that exhibit very diverse effects. Many of these symbionts are mutualists and bring important advantages to their hosts, notably through the complementation of their diet. Others manipulate the reproduction of their host to their own advantage. Such manipulations include feminization of genetic males, male-killing, induction of parthenogenesis or cytoplasmic incompatibility. These two types of symbiosis have classically been studied separately, but recent advances show that this dichotomy is not as pertinent as previously thought. First, it is becoming clear that reproductive manipulators can also provide advantages to their hosts. Second, some examples show that the dependence of the host upon its symbiont may rapidly evolve even when the symbiont does not bring benefit to its host, either through conflict resolution or evolution of tolerance. Finally, evolution of dependence may also explain why infection by multiple symbionts within the same host may persist in the long term. These results provide interesting new scenarios for the evolution of obligatory host-symbiont relationships and the building of complex symbiotic communities. They suggest that dependence can emerge from different evolutionary routes and may stabilize host-symbionts interactions.

Tsetse-*Wolbachia* symbiotic associations

Konstantinos Bourtzis
University of Western Greece, Greece

Wolbachia is a widespread and highly diverse group of alphaproteobacteria infecting arthropod and filarial nematode species. These symbionts are frequently found as intracellular and maternally inherited symbionts in insect species, whose reproductive properties they manipulate by inducing cytoplasmic incompatibility (CI), parthenogenesis, male-killing and feminization. Due to their unique biology, Wolbachia symbiotic associations are currently being considered as promising tools for the control of agricultural pests and medical disease vectors, including Glossina sp., which transmit African trypanosomes, the causative agents of the sleeping sickness in humans and of nagana in animals. In the present study, we report on recent studies on the detection and characterization of Wolbachia infections in laboratory and natural populations of Glossina species, the horizontal transfer of Wolbachia genes to tsetse chromosomes and also on how Wolbachia symbiosis could be harnessed for the development of novel symbiont-based pest and disease control strategies.

Symbionts and fitness of Tephritid fruit flies

Boaz Yuval
Hebrew University, Israel

I will review recent work on the relationship between true fruit flies (Diptera: Tephritidae) and their associated microorganisms. Mediterranean fruit flies (Ceratitis capitata), harbor a diverse community of bacteria in their digestive system. Molecular and culture- based techniques show that members of the Enterobacteriaceae form the dominant populations in the medfly's gut. Among them, many are diazotrophs and actively fix nitrogen in vivo. Most prominent are Klebsiella spp, Enterobacter spp., Pectobacterium spp. Citrobacter freundii and Providencia stuartii. A marked shift in community composition was observed between different developmental stages: in larvae, the pectinolytic Pectobacterium were most abundant, suggesting that pectinolysis plays a role early during the fly's life. The presence of the intact bacterial community is significantly associated with egg laying in females, mating success in males and longevity in both sexes. The closely related olive fly (Bactrocera oleae), is intimately associated with one microorganism - Ca. Erwinia dacicola. This species contributes to adult nutrition by supplying essential amino acids, and allows larvae to overcome the phytochemical defenses of the olive. In conclusion, the association between bacteria and fruit flies is intricate and multi-faceted, yet evidence for interdependence between hosts and symbionts is very strong. Further research will unravel the specific manner whereby bacteria contribute to the fitness of their host, and how this association may be manipulated in control operations.

Identification of a new secondary symbiont in the whitefly *Bemisia tabaci* (Hemiptera: Aleyrodidae)

Xiao-Li Bing[1], Jiao Yang[2], Shu-Sheng Liu[3], Xiao-Wei Wang[4]

[1]Zhejiang University, China, [2]Zhejiang University, China, [3]Zhejiang University, China, [4]Zhejiang University, China

The whitefly Bemisia tabaci (Hemiptera: Aleyrodidae) is a species complex containing > 20 cryptic species some of which are important crop pests worldwide. Like many other sap-sucking insects, whiteflies harbour an obligatory symbiont Candidatus Portiera aleyrodidarum and a number of secondary symbionts. So far six types of secondary symbionts have been identified in B. tabaci including Hamiltonella, Arsenophonus, Wolbachia, Rickettsia, Cardinium and Fritschea spp. In this study, we found a novel bacterium in the indigenous B. tabaci cryptic species China 1 (previously known as B. tabaci biotype ZHJ3). Phylogenetic analysis based on the 16S rRNA gene showed that the bacterium belongs to the α-subdivision of the Proteobacteria and has a relationship with human pathogens Orientia spp. and secondary endosymbionts of the wheat aphids Sitobion miscanthi and Rhopalosiphum padi. As a result, we temporarily describe it as Orientia like organism (OLO). OLOs were found in 7 of 9 wild populations of B. tabaci cryptic species China 1 with an infection rate from 46.2% to 76.8%. Fluorescence in situ hybridizations (FISH) in nymphs and adults of B. tabaci China 1 revealed that OLOs are confined in the bacteriome and co-localize with Ca. Portiera aleyrodidarum. This study broadens the diversity of symbionts detected so far in B. tabaci.

Molecular and cellular mechanisms of self-sacrificing gall repair by soldier nymphs in the social aphid

Mayako Kutsukake
National Institute of Advanced Industrial Science and Technology (AIST), Japan

Together with bees, wasps, ants and termites, aphids contain many social species with individuals altruistic to their colony mates, called soldiers. In the social aphid Nipponaphis monzeni, gall repair is among the important tasks of soldiers for colony defense. N. monzeni forms completely closed galls on the tree Distylium racemosum. Although closed galls are generally resistant to predators, some gall-feeding specialists such as moth larvae often invade the gall by tunnelling through the wall. When a hole is bored on the gall wall, the soldier nymphs immediately gather around the hole, discharge a large amount of body fluid from their cornicles on the damaged area, and mix the fluid with their legs. The discharged fluid soon becomes viscous and solidifies, whereby the hole is filled up completely. In an attempt to understand the molecular basis of this behavior, especially the mechanism of the body fluid solidification, we analyzed protein components of the secretion. We found that the secretion contained six major components, one of which was phenoloxidase, a key enzyme involved in melanization and scab formation in insects. The phenoloxidase was expressed in peculiar, soldier-specific "large globular cells" that occupied the body cavity of the soldier nymphs. RNA sequencing analysis of the large globular cells revealed that many genes involved in the process of melanization were predominantly expressed in these cells. We suggest that aphid's innate immune and wound-healing mechanisms might have been enhanced and recruited to the social task, gall repair, in the lineage leading to N. monzeni.

The genome of the socially-polymorphic halictid bee, *Lasioglossum albipes*

Sarah D Kocher[1], Guojie Zhang[2], Li Cai[3], Hopi E Hoekstra[4], Naomi E Pierce[5], Douglas Yu[6]

[1]Harvard University, U.S.A., [2]BGI, Shenzhen, China, [3]BGI, Shenzhen, China, [4]Harvard University, United States Minor Outlying Islands, [5]Harvard University, U.S.A., [6]Kunming Institute of Zoology School of Biological Sciences, University of East Anglia, China

Halictid bees, or "sweat" bees (family Halictidae), are an ideal system to study social behavior because they span the entire range of behaviors, from solitary to eusocial. Within this monophyletic family, there have been at least three independent origins of eusociality and many subsequent losses. As a result, the behavioral variation within this group encapsulates nearly all forms of social structure, including solitary, communal, and primitively eusocial species. Our work focuses on the halictid bee, Lasioglossum albipes. L. albipes exhibits variation in social structure across its range; some populations are primitively eusocial while others are solitary. Previous studies have demonstrated that this behavioral polymorphism is the result of a reversion from eusocial to solitary behavior, and that it has a strong genetic component. We are using population and evolutionary genomic approaches to identify some of the genetic and environmental variables associated with social behavior in this system. We have recently completed a draft genome assembly for this species, and discuss these results in a comparative genomic framework using available data from other social insect species.

Genomics of pheromone communication in honey bees

Osnat Malka[1], Lastro Elina[2], Grozinger Christina[3], Hefetz Abraham[4]

[1]Tel Aviv University, Israel, [2]Tel Aviv University, Israel, [3]Tel Aviv University, Israel, [4]Tel Aviv University, Israel

A main objective in the study of social evolution is to understand how the social environment indirectly influences the expression of socially relevant traits. Social life influences many biological functions including reproduction, foraging and protection against predators. Such traits are controlled by the genotype of an individual as well as by social partners. In the honeybee, Apis mellifera, sociality relies on chemical communication to regulate several aspects of colony life. Caste specific pheromones are the hallmark of social insects. In the honeybee these pheromones regulate a plethora of behaviors, including the absolute reproductive dominance of the queen. The mandibular pheromone provides an excellent system for studying social communication processes at the gene level, in particular the expression of caste specific pheromones. To underline these, we performed a microarray study of the mandibular glands of queens, queenright (QR) workers and queenless (QL) workers. About 2554 genes were significantly expressed in the glands. The genes transcripts whose expression patterns were correlated with caste, revealed an overrepresentation of processes associated with oxidation-reduction activity, immune response, and several metabolic and biosynthetic processes. The genes transcripts whose expression patterns were significantly different between QL and QR workers (reflecting social environment), revealed an overrepresentation of genes associated with protein catabolism. In this study we make predictions about the biosynthetic steps and enzymes involved in the production of fatty acid based pheromones in the mandibular gland. Out of the 2554 significant regulated transcripts, we identified 32 genes that may play a role in pheromone biosynthesis.

100 million years of social evolution ? Lessons learned from seven ant genomes

Juergen Rudolf Gadau[1], Martin Helmkampf[2], Sanne Nygaard[3], Julien Roux[4], Daniel F. Simola[5], Chris R. Smith[6], Garret Suen[7], Yannick Wurm[8], Christopher D. Smith[9]

[1]Arizona State University, U.S.A., [2]Arizona State University, U.S.A., [3]University of Copenhagen, Denmark, [4]University of Lausanne, Swiss Institute of Bioinformatics/University of Chicago, U.S.A., [5]University of Pennsylvania, U.S.A., [6]Earlham College, University of Wisconsin-Madison, U.S.A., [7]University of Wisconsin-Madison, U.S.A., [8]University of Lausanne, Swiss Institute of Bioinformatics, U.S.A., [9]San Francisco State University, U.S.A.

The genetic and genomic changes associated with the evolution, maintenance, and regulation of eusociality is currently not well understood in part because so far only one sociogenome (honeybee) was available. Building upon the recent sequencing of seven ant genomes we performed a comparative analysis of the genomic organization of two insect lineages that convergently evolved eusociality (bees and ants) and other solitary insects (Gadau et al. 2011). Ant genomes differ in many fundamental aspects from the honeybee genome , e.g. gene number, lineage specific genes, DNA methylation, miRNA composition, transcription factors, and transcription factor binding sites. Additionally, ant evolution over the past 10-100 million years has also lead to dramatic genomic reorganizations between the seven ants both in terms of gene composition and regulation.

What makes a termite queen: Genes involved in maintaining reproductive division of labour

Johannes Gowin[1], Judith Ingrid Dr Korb[2]
[1]*University of Osnabrueck, Germany,* [2]*University of Osnabrueck, Germany*

Reproductive division of labour is the hallmark of insect sociality. It evolved in termites, as social cockroaches, independently from the social Hymenoptera. We study its molecular underpinning in a lower termite, Cryptotermes secundus. Here workers are totipotent and can explore all caste options: becoming a soldier, an inheriting replacement reproductive or a winged dispersing reproductive. With use of cDNA representational difference analysis, we identified five genes (Neofem1-5) which are significantly overexpressed in queens compared to workers. Applying a combination of RNA interference (RNAi), behavioural assays, endocrinological studies and GC MS analyses we tested two of these genes for their functional significance. We could show that inhibiting Neofem2 and Neofem4 makes workers behave as though the colony is queenless and that they are necessary for the queen to suppress worker reproduction. Neofem2's putative gene product suggests that it is a β-glycosidase. RNAi of Neofem4 also resulted in a change of the cuticular hydrocarbon profile of the treated queen, so that her smell was more worker-like. These results suggest that Neofem4 is involved in the production of the royalty scent that assures the reproductive monopoly of the queen.

Genomics of social behavior in fire ants

John Wang
Academia Sinica, Taiwan

The fire ant Solenopsis invicta is characterized by a remarkable form of social polymorphism, with the presence of one or several queens per colony being completely associated with allelic variation at a single Mendelian factor marked by the gene Gp-9. Because additional phenotypic differences in physiology, fecundity, and behavior are also completely associated with Gp-9, it has been hypothesized that the locus is actually comprised of multiple genes that form a supergene. To test this possibility, we mapped the monogyny/polygyne social polymorphism to higher resolution using restriction-site associated DNA (RAD) tag sequencing, which is a recently developed method that permits rapid SNP discovery and genotyping at low cost. By taking advantage of the recently completed draft genome sequence for fire ants, we were able to anchor many of the RAD tags to the genome, and we found that Gp-9 is associated with a non-recombining region covering ~13 Mb and corresponding to ~2/3 of the chromosome. Thus, variation in colony social form in fire ants is associated with a very large supergene which we propose to be a social chromosome.

Sociogenomics of conflict and cooperation in fire ant queens

Fabio Manfredini[1], Oksana Riba Grognuz[2], Yannick Wurm[3], Laurent Keller[4], DeWayne D. Shoemaker[5], Christina M. Grozinger[6]

[1]The Pennsylvania State University, U.S.A., [2]University of Lausanne, Switzerland, [3]University of Lausanne, Switzerland, [4]University of Lausanne, Switzerland, [5]USDA-ARS Gainesville, U.S.A., [6]The Pennsylvania State University, U.S.A.

Founding behavior is a key feature of life history in social insects and one of the best examples of behavioral plasticity, since young queens can often adopt multiple strategies of colony foundation within the same species. Newly mated queens of the fire ant Solenopsis invicta can found new colonies alone (haplometrosis) or in group (pleometrosis). Here, the initial cooperation among queens, useful to defend the incipient colony against enemies and to increase the size of the colony more quickly, turns into conflict as soon as the first workers are close to emergence. Only one queen will be allowed to lead the mature colony while the others will die in fights with the dominant queen or as a consequence of the repeated aggressions performed by workers. We developed a microarray platform to monitor the expression of ~50K probes: these include a set of ~16K genes annotated from the Solenopsis invicta genome project, and a set of ESTs obtained from transcriptomic studies. We characterized the expression patterns in haplometrotic and pleometrotic queens. Counterintuitively, we found that the social context is more important than the outcome of the conflict: pleometrotic queens have very similar gene expression compared to haplometrotic queens. Moreover, changing the social status in pleometrotic queens from winner to loser and vice-versa triggers larger changes in gene expression than the social status itself. This means that the social environment is the major force driving gene expression in pleometrotic queens and its drastic manipulation produces effects at the genomic level.

Immunity in social insects: Insights from two Bombus genomes

Seth Barribeau[1], Ben Sadd[2], Paul Schmid-Hempel[3]

[1]Institute of Integrative Biology, ETH Zurich, Switzerland, [2]Institute of Integrative Biology, ETH Zurich, Switzerland, [3]Institute of Integrative Biology, ETH Zurich, Switzerland

Group living offers considerable benefits but not without some obvious costs. In particular, high sociality comes with a greater risk of infection, especially when the groups are genetically homogenous, as in many social insects. Surprisingly, the first hymenopteran genome, the honeybee, revealed a reduced immune system relative to existing model insect species. Honeybees and many other highly social insects have complex, and highly successful behavioral defenses against parasites, which might compensate for this reduced immune repertoire. Since the sequencing of the honeybee genome, the solitary wasp Nasonia, a suit of ants, and now two bumblebee genomes have been sequenced which vary in complexity of sociality. We discuss immunity in bumblebees revealed by the two recently sequenced genomes in the context of sociality.

Insects as micro-scale biomass conversion systems and diversity of their lignocellulolytic enzymes

Hirofumi Watanabe
National Institute of Agrobiological Scinences, Japan

Sizes of insects and their bioplans are generally suit for biomass processing. Their physical breaking-down systems, which consisted of the mandibles and the proventriculus of rigid cuticular structures, are ideal not only for herbivory but also for xylophage. The body sizes of xylophagous species allow them to dig into soft parts of wood avoiding highly lignified parts (heartwood and summer wood). The basic enzymatic digesting systems of xylophagous insects consist of endogenous enzymes mainly of GHF (glycoside-hydrolase family) 9 (hemimetaboly species), 5&45 (coleopteran species), although other family members have found as minor components including those of unknown functions. These endogenous enzymes are considered to digest surface area of exposed cellulose fibrils by the physical breaking of lignocellulose matrix to quickly supply physiologically required glucose of minimum amounts. For further comprehensive digestion of lignocellulose, many species, especially lower termites, combine a symbiotic digestive system in addition to the endogenous system (or seem to totally depend on ectosymbiotic cellulolytic fungi as is the case of Ambrosia beetles). The ligunocellulytic digestion of the termite symbiotic protozoa are considered as totally intracellular process isolated from the extracellular space, so mode of actions of possible synergistic effects with the endogenous enzymes are argued including presence/absence of such effects. In addition, the pretreating effect of possible endogenous proteins/substances of the termite salivary glands is also on the discussion with anecdotal/empirical evidences, which has not been reported with molecular proofs so far.

A comprehensive dissection of lignocellulolytic enzymes in a wood-feeding cockroach, *Cryptocercus punctulatus*

Xiangrui Li[1], Xuguo Zhou[2]
[1]*Chinese Academy of Agricultural Science, University of Kentucky, U.S.A.,* [2]*University of Kentucky, U.S.A.*

As fossil fuels are being depleted, much attention has turned to the most abundant carbohydrate energy resources on Earth, lignocelluloses, a naturally occurring complex of plant-derived materials that includes hydrophilic sugar polymers cellulose and hemicellulose, and a hydrophobic organic "glue"- lignin. Wood-feeding insects have intrigued scientists for decades because of their unique capability of breaking down the lignocellulose matrix of cellulose, hemicelluloses, and lignin in plant cell walls. The pressing needs for bioenergy and biomass conversion have redirected termite research to focus more on lignocellulose digestion and degradation. However, there is virtually no information available on the termite sister group, a wood-feeding cockroach punctulatus , which has more diversified cellulolytic symbionts than termites. To search for novel lignocellulolytic enzymes, we have initiated a tissue-specific metagenome-transcriptome sequencing project to inventory a comprehensive set of genes from both hosts and symbionts which potentially involved in the lignocellulose degradation as well as nitrogen recycling in the wood-feeding C. punctulatus. Such an effort would facilitate discovery and functional analysis of novel cellulolytic enzymes as well as provide sequence information on the nitrogen fixation by prokaryotic symbionts reside in the woodroach hindguts. These discoveries will be critical to breakthroughs in better understanding of nitrogen recycling in the ecosystem and potentially to improve the production of renewable energy through the discovery of novel cellulolytic enzymes that could contribute to the enzymatic pretreatment processes.

Its intestinal microbial metagenome is believed to be a reservoir for new lignocellulases. Functional -based gene screenings of metagenomic libraries have been employed to obtain genes or gene clusters directly from environmental DNA. In our recent study, we combined a refined intestinal microbial DNA extraction method and multiple-displacement amplification (MDA) to obtain enough high quality and quantity of intestinal microbial DNA from termite guts. Two fosmid libraries were then constructed from the total microbial DNA isolated from the guts of a fungus-growing termite and a higher wood-feeding termite, respectively. Functional screening for endoglucanase, cellobiohydrolase, glucosidase and xylanase resulted in more than 400 positive clones. In total, about 200 of the positive ones were sequenced by the high throughput pyrosequence approach, and about 120 unique GH genes were annotated, the sequences of which were matched to the nearest GH genes in databases ranged from 29% to 76%. Fifty of the screened GH genes were expressed in E. coli and about 24 purified enzymes were obtained. The characteristics of the purified enzymes, including the optimal pH values and temperatures, the ranges of pH tolerance, thermostability and specific substrate activities, were investigated. § the presenting author

Integration of the lignocellulolytic systems of insects to biofuels industries

Jianzhong Sun
Jiangsu University, China

Lignocellulose is the most abundant form of biomass on the planet and is a renewable resource that can serve as a feedstock for fuels and chemicals. It has been noted that the life systems with the function to efficiently degrade lignocellulosic biomass are very rare on the earth although many of the microbial systems (such as bacteria and fungi) would chronically degrade lignocellulosic biomass. However, after experiencing a long period of evolution, some wood-feeding insects have developed an incredible function to efficiently deconstruct lignocellulosic polymers from agricultural crops to forest woody substrates and rely on lignocellulosic biomass as their only foods. Cellulose digestion has been demonstrated in more than 20 families representing ten distinct insect orders, e. g. Thysanura, Plecoptera, Dictyoptera, Orthoptera, Isoptera, Coleoptera, Trichoptera, Hymenoptera, Phasmida, and Diptera. The ability of these insects to feed on wood, foliage and detritus has recently stimulated extensive investigations into the mechanisms of how these insects digest the structural and recalcitrant lignocellulose in their foods. This review addresses various lignocellulolytic systems, their potential values, challenges, and opportunities that exist for scientists and industries to advance the biofuel technology, where the following topics will be further addressed: 1) Scientific and industrial potentials of the natural biomass utilization systems; 2) Novel biocatalysts explored from natural biomass utilization systems and their engineering potential for industrial uses; 3) Novel microbial symbionts discovered from natural biomass utilization systems by "omics" technologies; 4) Bioreactor innovations mimicked and advanced from the efficient biomass utilization systems.

Digestion from within: Improving biomass feedstock through engineering multifunctional lignocellulose degrading enzymes using termite and wood roach lignocellulases

Ling Yuan[1], Xuguo Zhou[2]

[1]*University of Kentucky, U.S.A.*, [2]*University of Kentucky, U.S.A.*

The development of an enzyme-based biomass pretreatment system that would allow pretreatment under moderate temperatures and mild pH is attractive. However, biological processing of biomass requires a large number of lignocellulosic enzymes that are expensive to produce at industrial scales. One approach, which may simplify the pretreatment step, is to "digest from within" through the production of lignocellulosic enzymes in plant feedstock.Termites and their relatives, including the wood-eating cockroaches, can efficiently convert 95% of the recalcitrant lignocelluloses into fermentable sugars in their tiny bioreactor hindguts in less than 24 hours. Such efficiency and low energy inputs make the insect lignocellulases an ideal enzyme source for biomass pretreatment. Recently, we have applied genomic and proteomic tools to identify over 600 lignocellulase genes from the insect gut microfauna and functionally characterized several key genes in the lignocellulose digestion machinery. Previously, we have generated a number of chimeric lignocellulosic hydrolases that contain two to five functional modules joined by peptide linkers. These chimeras closely resemble the parental enzymes in kinetics and other enzymatic properties, and some exhibit improved synergy in degrading natural substrates when compared to mixtures of parental enzymes. Our overall hypothesisisplant feedstock can be optimized for pretreatment and saccharification through the "built-in" lignocellulases. Using the novel chimeric enzymes for this purpose is advantageous as they can simplify vector construction, downstream crop analysis and breeding.

Profiling the mosquito transcriptome: Case studies of *Aedes aegypti* and *Anopheles gambiae*

Mariangela Bonizzoni[1], William Augustine Dunn[2], Corey L Campbell[3], Ken E Olson[4], Osvaldo Marinotti[5], Guiyun Yan[6], Anthony A James[7]

[1]University of California at Irvine, U.S.A., [2]University of California at Irvine, U.S.A., [3]Colorado State University, U.S.A., [4]Colorado State University, U.S.A., [5]University of California at Irvine, U.S.A., [6]University of California at Irvine, U.S.A., [7]University of California at Irvine, U.S.A.

The understanding of gene expression profiles of organisms under defined conditions and stimuli offers the possibility to uncover the complex metabolic pathways and gene interactions contributing to the phenotype. Additionally, from a vector control perspective, this strategy allows the identification of: 1- key targets for monitoring the acquisition of a phenotype such as insecticide resistance; 2- cis-regulatory regions that could be co-opted to create transgenic pathogen-refractory insects. The recently-emerged RNA-seq technology was applied to study the expressional response of different strains of the dengue vector mosquito, Aedes aegypti following a blood meal and during dengue infection and the comparative transcriptomics of insecticide -resistant and -susceptible Anopheles gambiae mosquitoes.

Application of functional genomics and transcriptomics to understanding lactation in the tsetse fly (*Glossina morsitans morsitans*)

Geoffrey Michael Attardo[1], Joshua Benoit[2], Veronika Michalkova[3], Serap Aksoy[4]

[1]Yale School of Public Health and Epidemiology, U.S.A., [2]Yale School of Public Health and Epidemiology, U.S.A., [3]Yale School of Public Health and Epidemiology, U.S.A., [4]Yale School of Public Health and Epidemiology, U.S.A.

The tsetse fly is a unique insect and disease vector due to its unusual biology. The viviparous reproductive biology and lactation system the fly has developed is particularly interesting. In this work we combine the power of transcriptomic analysis by RNA-seq with the recently completed tsetse genome sequence to identify and annotate tsetse specific milk proteins, regulatory elements driving lactation specific gene expression and regulatory factors driving milk protein gene expression. RNA-seq analysis of lactating females versus non-lactating females allowed global identification of differential gene expression during pregnancy. This analysis confirmed the up regulation of previously identified milk proteins in lactating flies and identified a suite of novel tsetse milk proteins. The expression profile of all these genes is milk gland and larvigenesis specific. Transgenic analysis of the regulatory region for the major milk protein GmmMGP1 in Drosophila shows that this region drives female accessory gland specific gene expression during reproduction. In silico comparison of this regulatory region with the genome derived upstream regulatory regions of known and novel milk proteins identified conserved homeodomain type transcription factor binding site predictions. We identified 96 putative tsetse homeodomain proteins from the genome. Of the 96, 6 are differentially expressed in pregnant flies as predicted by the described RNA-seq data. Expression and tissue specific analysis of these six proteins identified a single homeodomain gene (Ladybird Late) as specific to the milk gland tissue. Knockdown of this factor resulted in an ~80% reduction of milk protein gene expression in pregnant females.

Sexual maturation and mating in insects are generally accompanied by major physiological and behavioural changes. Many of these changes are related to the need to locate a mate and subsequently, in the case of females, to switch from mate searching to oviposition behaviour. The prodigious reproductive capacity of the Mediterranean fruit fly, Ceratitis capitata, is one of the factors that has led to its success as an invasive pest species. To identify the molecular changes related to maturation and mating status in male and female medfly, a microarray-based gene expression approach was used to compare the head transcriptomes of sexually immature, mature virgin, and mated individuals. Attention was focused on the changes in abundance of transcripts related to reproduction, behaviour, sensory perception of chemical stimulus, and immune system processes. Broad transcriptional changes were recorded during female maturation, while post-mating transcriptional changes in females were, by contrast, modest. In male medfly, transcriptional changes were consistent both during maturation and as a consequence of mating. Of particular note was the lack of the mating-induced immune responses that have been recorded for Drosophila melanogaster, that may be due to the different reproductive strategies of these species. This study, in addition to increasing our understanding of the molecular machinery behind maturation and mating in the medfly, has identified important gene targets that might be useful in the future management of this pest.

Cell death genes and their use in Tephritid pest control

Marc F Schetelig[1], Alfred M Handler[2]
[1]USDA-ARS, U.S.A., [2]USDA-ARS, U.S.A.

Pro-apoptotic proteins from the reaper, hid, grim (RHG) family are primary regulators of programmed cell death in Drosophila due to their antagonistic effect on inhibitor of apoptosis (IAP) proteins, thereby releasing IAP inhibition of caspases that effect apoptosis. Using a degenerate PCR approach to conserved domains from the 12 Drosophila species, we have identified the first reaper and hid orthologs from a tephritid, the Caribfly Anastrepha suspensa. As-hid is the first identified non-drosophilid homolog of hid, and As-rpr is the second non-drosophilid rpr homolog. Both genes share more than 50% amino acid sequence identity with their Drosophila homologs, suggesting that insect pro-apoptotic peptides may be more conserved than previously anticipated. In addition, these tephritid cell death genes could be used as functional and potent as cell death effectors, and to design improved transgenic lethality systems for insect population control.

Genome annotation and functional genomics of insect olfactory binding proteins

Jing- Jiang Zhou[1], Linda Mary Field[2]

[1]Rothamsted Research, United Kingdom, [2]Rothamsted Research, United Kingdom

Olfaction plays a crucial role in insects' attraction to hosts and mates. Although the molecular basis of this interaction is not well understood it is likely that olfactory binding proteins (OBP) are involved in the first step of molecular recognition. We have defined OBP-specific sequence motifs based on highly conserved cysteine residues, developed an algorithm which has allowed us to identify genes encoding putative OBPs from several insect genome sequences and classified OBPs into Classic, Atypical, Plus-C, Minus-C and CSP subfamilies. Phylogenetic analyses showed a high conservation among Lepidoptera OBPs but a rapid expansion and high divergence of DipteraOBPs. Comparative analyses of OBP sequences reveal some mosquito-specific genes as well as conserved homologs with OBPs of other insects. The analyses of OBP-containing regions for microsynteny indicate a very high synteny between Aedesaegyptiand Anopheles gambiae. Our genome wide analysesof insectOBPs suggest that the rapid expansion and high divergence of DipteraOBPs have occurred probably by gene duplication after speciation. The genome of the parasitoid wasp Nasoniavitripennis contains the largest OBP family (90 members) so far reported in insects, and a new lineage specific domain arrangements, such as the double domain OBP subfamily of wasps and mosquitoes. qRT-PCR revealed that some OBP genes were highly transcribed in the antennae but also in other tissues. Expression of chemosensory proteins in the tsetse flyGlossinamorsitansmorsitans is related to female host-seeking behaviour.

The genome of *Clunio marinus* (Chironomidae, Diptera): A marine insect gives insights into circalunar and circadian clocks

Tobias S Kaiser[1], Lam-Tung Nguyen[2], Tobias Neumann[3], Arndt von Haeseler[4], Kristin Tessmar-Raible[5]

[1]Max F Perutz Laboratories, Austria, [2]University of Vienna and Medical University of Vienna, Austria, [3]Max F Perutz Laboratories, Austria, [4]University of Vienna and Medical University of Vienna, Austria, [5]Max F Perutz Laboratories, Austria

The marine midge Clunio marinus has precisely timed its life cycle to the tides by a combination of diurnal and lunar rhythms. Tidal regimes differ along the coast and local populations show corresponding genetic adaptations. Population genetic examination showed that the timing adaptations are of recent and common origin. Crossing experiments and QTL mapping revealed the loci underlying the timing adaptations, giving first insight in the genetics of circalunar clocks and their interaction with circadian clocks. In summary, Clunio is an exciting model for chronobiology and evolutionary genetics. We have now sequenced the Clunio marinus genome, using a genetic map as a backbone for genome assembly. The genome is <100 Mb in size and has ~70% AT content. Comparative sequencing of DNA pools from two field populations identified 586,422 SNPs, but only 1,359 (0.2%) of these are differentially fixed between populations. This underpins recent evolutionary divergence of populations and hints to which genes control functional differences, e.g. regarding the above-mentioned timing traits. Beyond, the genome sequence enables many other studies: Clunio is strikingly sexually dimorphic, females having reduced wings, legs, eyes and antennae. During secondary colonization of marine habitats Clunio has evolved water-repellent surfaces and tight osmoregulation. To date there is no other chironomid genome published. The closest sequenced relatives (Aedes, Culex, Anopheles) are ~220 million years divergent. Thus, the Clunio genome may aid the study of other chironomids (which are e.g. indicator species in ecotoxicology and climate reconstruction) and is a valuable resource for comparative insect genomics.

The mode of action of dsRNA for control of western corn rootworm (*Diabrotica virgifera virgifera*) larvae

Renata Bolognesi[1], Parthasarathy Ramaseshadri[2], Ronnald Flannagan[3], William Moar[4], Gerrit Segers[5]

[1]Monsanto Company, U.S.A., [2]Monsanto Company, U.S.A., [3]Monsanto Company, U.S.A., [4]Monsanto Company, U.S.A., [5]Monsanto Company, U.S.A.

Double-stranded RNA (dsRNA) is known to be effective in Diabrotica larvae via oral delivery. After ingestion, the dsRNA is thought to be taken up by the insect midgut cell and processed by the native RNAi machinery, which leads to specific knockdown of the target mRNA. The knockdown effect can cause lethality if the target mRNA encodes a protein with an essential function in the insect. Although processing of the dsRNA and target mRNA degradation appear to be conserved in western corn rootworm, some of the key steps in this process, such as uptake of dsRNA into midgut cells, are still unknown. In this presentation, we will present data on the dsRNA uptake mechanism and its selectivity for molecules of different sizes, as well as, the detailed morphological and cellular defects that lead to western corn rootworm (WCRW, Diabrotica virgifera virgifera) death upon ingestion of dsRNA targeting an essential gene.

RNAi-aided baculovirus resistance in the transgenic silkworm: Application to sericulture

Javaregowda Nagaraju[1], E V Subbaiah[2], C Royer[3], S Kanginakudru[4], A Sobhan Babu[5], V V Satyavathi[6], P J Raju[7], B Mauchamp[8], G Chavancy[9], P Couble[10]

[1]Centre for DNA Fingerprinting and Diagnostics (CDFD), India, [2]Centre for DNA Fingerprinting and Diagnostics (CDFD), India, [3]INSA de Lyon, France, [4]Centre for DNA Fingerprinting and Diagnostics (CDFD), India, [5]Centre for DNA Fingerprinting and Diagnostics (CDFD), India, [6]Centre for DNA Fingerprinting and Diagnostics (CDFD), India, [7]Andhra Pradesh State Sericulture Research and Development Institute (APSSRDI), India, [8]INSA de Lyon, France, [9]International Silk Commission, France, [10]Universite Claude Bernard, France

Bombyx mori Nuclear Polyhedrosis Virus (BmNPV) infection is a major cause of silk cocoon crop losses in sub-tropical sericulture. Our earlier attempts to confer resistance to baculovirus infection by constructing silkworm transgenic lines carrying transgene encoding double stranded RNA for the essential viral gene, ie-1 proved rather efficient in preventing baculoviral infection (Kanginakudru et al. 2007 Insect Molecular Biology 16, 635-644). However, the transgenic lines were not robust enough to be exploitable in sericulture farms. We then constructed transgenic silkworms expressing short interfering RNAs (siRNAs) targeting several viral genes simultaneously, expecting that this would mount higher levels of baculoviral inhibition. Several transgenic lines, expressing siRNAs for four essential genes of the baculovirus, carrying transgenes expressing either sense (S), antisense (AS) or the double strand (DS) forms of the mosaic sequence were made. Very high level resistance to BmNPV was observed in the DS lines, as compared to the S, AS and their hybrid lines. Biochemical experiments suggested that the host-mediated RNAi machinery generates siRNAs in the transgenic lines. We then introgressed siRNA expressing transgene to the commercial but baculoviral susceptible Indian silkworm strain. Recurrent back-cross breeding coupled with microsatellite marker-aided selection led to the successful introgression of baculovirus resistance property to the high yielding strain. These transgenic lines are undergoing laboratory trials pending clearance from the Indian Govt for large scale field trials. This approach shows that the RNAi pathway can be successfully exploited in developing baculovirus resistant silkworm strains and that this could find commercial applications in sericulture.

Identification of fecundity related genes of the brown plant hopper through RNA interference

Wenqing Zhang[1], Jianqing Zhang[2], Yifan Zhai[3], Jing Chen[4], Rong Yu[5], Yuan He[6], Xiaolin Dong[7]

[1]Sun Yat-sen University, China, [2]Sun Yat-sen University, China, [3]Sun Yat-sen University, China, [4]Sun Yat-sen University, China, [5]Sun Yat-sen University, China, [6]Sun Yat-sen University, China, [7]Sun Yat-sen University, China

The brown plant hopper, Nilaparvata lugens (Stal), is one of the most serious rice insect pests in many parts of Asia. After established a feeding-based RNAi method for this pest, it was used to identify functions of several fecundity related genes such as vitellogenin (Vg) gene, forkhead transcription factor (FoxA) and ecdysteroid receptor (EcR) gene. FoxA is required for ovarian mature in this insect. Rice-mediated RNAi experiments indicated that silencing of EcR gene decreased number of offspring by 34%-78%. RNASeq analyses showed that 1639 genes were up-regulated in 5th instar nymphae and 7408 genes in day 2 female adults between high and low fecundity populations. By using proteomics techniques, 39 and 54 different proteins were found in day 3 and day 6 female adults, respectively. Based on bioinformatics analyses of above findings, about 100 genes were selected for further RNAi studies. It is expected that about 10 fecundity related genes will be identified which may be potential target genes for controlling insect pests.

RNAi for biological control

Teruyuki Niimi[1], Takahiro Ohde[2], Toshinobu Yaginuma[3]
[1]Nagoya University, Japan, [2]Nagoya University, Japan, [3]Nagoya University, Japan

The multicolored Asian ladybird beetle, Harmonia axyridis is a predator of numerous aphid species, and its use as a biological control agent has already been established. However, as adult beetles immediately tend to fly away from field crops, sustainable use in biological control has been restricted. To resolve this problem and make this biological control more efficient, a flightless strain that is unable to disperse from crops has been developed. We established a novel method to produce a flightless ladybird beetle for biological control using RNAi method which targets wing master genes. The injection of double-stranded RNA (dsRNA) for wing master genes into the larval body cavity of H. axyridis efficiently induced adult morphological defects that mimicked those of known loss-of-function phenotypes for these genes. As a consequence, wings were severely reduced and the ladybird beetles were flightless. The dsRNA injection did not have any obvious effect on the feeding behavior, and the voracious trait of H. axyridis remained unchanged. Thus, this RNAi method for flightless beetle production is very effective. As this RNAi method depends not on genetic transformation, but on posttranscriptional regulation, this biological control agent would be easily accepted by the public from an environmental and safety point of view. This technique opens sustainable use of flightless ladybird beetles in biological control and is widely applicable to other predators of pests for a biological control agent. Further, we should be able to design a "tailor-made insect" for ideal biological control using RNAi.

RNAi of transcription factor BmPOUM2 for regulation of development of silkworm wing dics during metamorphosis

Huimin Deng[1], Jialing Zhang[2], Yong Li[3], Sichun Zheng[4], Ling Liu[5], Lihua Huang[6], Qili Feng[7]

[1]South China Normal University, China, [2]South China Normal University, China, [3]South China Normal University, China, [4]South China Normal University, China, [5]South China Normal University, China, [6]South China Normal University, China, [7]South China Normal University, China

The wing cuticle protein gene BmWCP4 is regulated by the transcription factor BmPOUM2, which binds to the promoter of the BmWCP4 gene and activate its pupa-specific expression during metamorphosis in Bombyx mori. Quantitative real-time PCR (qRT-PCR) and western blotting analyses indicate that silencing the gene coding for BmPOUM2 by RNAi during the wandering stage resulted in suppression of BmWCP4 expression and a failure of last instar larvae to complete larval-pupal metamorphosis. The epidermis in the thorax region became transparent and the wing discs growth and differentiation was arrested. The RNAi larvae failed to spin cocoons. qRT-PCR analysis showed that expression of other pupa-specific wing cuticle protein genes BmWCP1, BmWCP2, BmWCP3, BmWCP5, BmWCP6, BmWCP8 and BmWCP9, as well as dopa decarboxylase, and sericin-1, were also down-regulated by BmPOUM2 RNAi in the BmPOUM2 RNAi animals. These data suggest that BmPOUM2 is a critical important transcription factor for the larval to pupal transformation in B. mori and it is involved in the regulation of the pupal-specific expression of BmWCP4, probably other BmWCPs as well, during metamorphosis. This project is supported by grants from the National Basic Research Program of China (2012CB114602) and the Chinese National Natural Science Foundation (31172265).

RNA interference to identify lethal genes involved in chitin metabolism of *Locusta migratoria*

Jianzhen Zhang[1], Daqi Li[2], Xiaojian Liu[3], Yaping Guo[4], Enbo Ma[5], Kun Yan Zhu[6]

[1]Shanxi University, China, [2]Shanxi University, China, [3]Shanxi University, China, [4]Shanxi University, China, [5]Shanxi University, China, [6]Kansas state university, U.S.A.

Chitin is widely distributed in epidermis and the peritrophic matrix of insects. The importance of chitin in insect development and the absence of chitin in vertebrates have led to a hypothesis of attacking insect chitin biosynthesis pathway as a novel target for developing safe and effective insecticides. The process of chitin biosynthesis and degradation consist of at least eleven key enzymes, but the roles of these enzymes in insect development have not been well elucidated. Five important genes putatively encoding trehalase 1 (TR1), glutamine: fructose-6-phosphate aminotransferase (GFAT), glucosamine-6-phosphate N-acetyltransferase (GNAT), UDP-N-acetylglucosamine pyrophosphorylase1 (UAP1) and chitin synthase 1 (CHS1). Have been identified to be involved in chitin biosynthesis in Locusta migratoria, In contrast, multiple chitinase genes and one β-N-acetylglucosaminidase gene have been identified to be involved in chitin degradation. By using RNA interference in different nymph stages, we observed that nymphs injected with dsRNA of GFAT, UDP1, CHS1, LmCht10 or LmNAG1 developed slowly, failed to detach from the old cuticle during molting process and showed high mortality. When the expression of LmCht10 was suppressed by RNAi, we found significantly reduced new cuticle development and cuticle thickness as compared with those of the dsGFP-injected controls. Our results suggest that GFAT, UDP1, CHS1, LmCht10 and LmNAG1 are essential for insect growth and development. The enzymes encoded by these genes could potentially serve as an excellent target for developing novel strategies for controlling this important pest.

Trichogramma genus is one of the most commonly used parasitoids in biological control programs. Several studies have proven that T. brassicae is the most dominant with most distribution in different regions of Iran. Thelytoky system base on Wolbachia infection has observed in this species. As for role of this bacterium in induction of thelytoky and importance of application of thelytokous species in biological control programs this study was conducted. Studying of behavior was conducted under controlled condition: 25±1°C, 50±10 % RH and 16:8 L: D. Individual Trichogramma females were presented with egg patches consisting of 100 host eggs glued with water on to a 5×5 cm white cardboard square with different host quality(100 fresh and old host eggs) separately. The host eggs were separated by a distance of 5 mm. A sequence of six behavioral events was used to monitor host use by the Trichogramma females. Spent time for oviposition on each fresh egg was 75±0.36 S, while this amount on old eggs was 79±0.98 s. Observed acceptance time for each fresh egg was 17±0.54 s but this time on old eggs was 18 ± 0.86 s. Rejection time of each fresh egg was 10±0.43 s and this parameter was 11±0.67 for each old egg.

What plant-produced volatiles should we target to improve biological control?

Ted Turlings
University of Neuchatel, Switzerland

An increasing number of studies suggest that natural plant defenses can be manipulated and exploited for the control of insect pests. We have been studying a form of indirect plant defense, whereby, in response to insect feeding, plants emit various volatile compounds that attract the natural enemies of their attackers. For instance, after caterpillar feeding, maize plants emit a blend of volatiles that is highly attractive to parasitic wasps, but our efforts to find ways to alter the emissions to increase attraction of parasitoids has so far failed, mainly because attraction is determined by minor, as yet unidentified compounds. We have had more luck with belowground interactions, where insects-damaged roots release attractants for entomophatogenic nematodes. The roots of many varieties of maize release the sesquiterpene (E)-?-caryophyllene when damaged by larvae of the voracious western corn rootworm. Interestingly, most North-American maize varieties do not emit this signal, which significantly reduces nematode attraction and dramatically lowers nematode infection rates of pest larvae. We used genetic transformation to restore the signal in an American line and in field trials found that this drastically improved the plant's ability to attract beneficial nematodes. Hence, improving plant signals can be an ecologically sounds strategy to fight crop pests. However, a full understanding of the other roles that such compounds may play in multitrophic interactions is necessary before they can be safely employed in pest control.

Selecting volatiles in the field to protect brassicaceous crops against the cabbage root fly, *Delia radicum*

Anne-Marie Cortesero[1], Alan Kergunteuil[2], Anne Le Ralec[3], Sebastien Dugravot[4]
[1]University of Rennes, France, [2]University of Rennes, France, [3]Agrocampus Ouest, France, [4]University of Rennes, France

Volatiles resulting from plant herbivore interactions play an important role in the behavioral decisions of phytophagous, predatory and parasitoid insects and could be used for managing pest insects. However, to date and after about 40 years of research, documented studies on applications in the field remain extremely scarce. Delia radicum, the cabbage root fly, is a major pest of brassicaceous crops for which classical control strategies are currently lacking. We have shown that dimethyl disulfide, a compound emitted by roots heavily infested by D. radicum larvae, was attractive for its main natural enemies and could lower the number of eggs laid on treated plants in the field by 60%. As a follow up of this work, we conducted another field study to select additional volatiles that could be used in a push-pull approach. Several synthetic HIPVs, selected on the basis of their potential action on the behavior of both the fly and its natural enemies, were placed in odor dispensers in experimental broccoli plots. Our results confirmed the role of dimethyl disulfide in reducing D. radicum egg numbers on broccoli plants and revealed other compounds that both influenced plant infestation by the fly and regulation by its main natural enemies. This study is a first step in designing a push-pull method to control the cabbage root fly but many steps need to be investigated before such a method can be implemented.

Induced plant semiochemical production to potentiate conservation biological control

John Anthony Pickett
Rothamsted Research, United Kingdom

In mainstream crop protection by conventional pesticides, integration of biological control can be conflicted. However, as we strive to deliver crop protection more sustainably via the seed, we can deploy pest control chemistry using the principles of chemical ecology that allow us not only to interfere with pest development, but also to potentiate biological control agents. With criticisms mounting against release of exotic biological control agents and rising costs of inundation approaches, conservation biological control is more appealing and can now effectively be manipulated by defence-related plant chemistry, enhanced through molecular breeding or genetic manipulation. A further refinement is to effect this semiochemical enhancement of conservation biological control, when needed, by induction using natural plant activators for this purpose. New work on these approaches will be discussed and further novel opportunities proposed.

Developing new measures for rice pest management via chemical elicitor-based manipulation of volatile signals

Yong gen Lou
Zhejiang University, China

Synthetic chemical elicitors of plant defense have been touted as a powerful means for sustainable crop protection. Yet, they have never been successfully applied to control insect pests in the field. We developed a high throughput chemical genetics screening system based on a herbivore-induced linalool synthase promoter fused to a GUS reporter construct to test synthetic compounds for their potential to induce rice defenses. We identified 2,4-dicholorophenoxyacetic acid (2,4-D), an auxin homologue and widely used herbicide in monocotyledonous crops, as a potent elicitor of rice defenses. Low doses of 2,4-D induced a strong defensive reaction upstream of the jasmonic acid (JA) and ethylene (ET) pathways, resulting in a marked increase of trypsin proteinase inhibitor activity and volatile production. Induced plants were more resistant to the striped stem borer Chilo suppressalis, but became highly attractive to the brown planthopper Nilaparvata lugens and its main egg parasitoid, Anugrus nilapavatae. In a field experiment, 2,4-D application turned rice plants into living traps for N. lugens by attracting parasitoids. Our findings demonstrate the potential of auxin homologues as defensive signals and show the potential of the herbicide to turn rice into a selective catch crop for an economically important pest.

How to improve a crop plant's ability to recruit of bodyguards?

Marcel Dicke
Wageningen University www.wur.ent.nl, Netherlands

Herbivorous arthropods are rarely pests in nature. However, in agriculture herbivorous arthropods cause significant losses. Our crops have been selected for a limited number of characteristics, especially related to product quality and quantity, in an environment where pests were eliminated by chemical control. Predators and parasitoids are important regulatory forces that limit herbivore populations below the economic injury level. To do so, these carnivorous bodyguards should be able to find their herbivorous victims at low densities. An important aid in finding their victims is to use herbivore-induced plant volatiles (HIPV). Although our crops have never been selected for the emission of HIPV they do emit these cues in response to herbivore infestation. Cultivars within a crop vary in the emission of HIPV and in the degree of attraction of carnivorous arthropods. This allows for the selection of cultivars that collaborate best with biological control agents. Alternatively, plant treatments may also influence the emission of HIPV and thus the attraction of bodyguards. In this presentation I will identify options to exploit knowledge on HIPV to improve a crop's ability to recruit its bodyguards.

Biological control using plant volatiles that attract specialist parasitic wasps of target pests

Masayoshi Uefune[1], Junji Takabayashi[2]
[1]Kyoto University, Japan, [2]Kyoto University, Japan

Plants emit so-called herbivore-induced plant volatiles (HIPVs) that attract carnivorous natural enemies of herbivores. We already reported that the synthetic blend of diamondback moth (Plutella xylostella) (DBM) larvae-induced cabbage plant volatiles attracted the specialist parasitic wasps Cotesia vestalis under both laboratory and field conditions. We show here that by setting the synthetic blend in greenhouses in a countryside agricultural field, we decreased the number of DBM larvae and increased the number of C. vestalis in greenhouses. We will discuss the possible use of synthetic blend of HIPVs for pest control.

Insect herbivory induces the synthesis and release of specific volatile compounds in plants. These volatiles have been shown to be highly attractive to natural enemies of the herbivores, such as predators, parasitic wasps or entomopathogenic nematodes. Few key compounds mediating these so-called tritrophic interactions are known, but in most cases they remain to be identified. In maize, the volatiles emitted upon feeding by leaf- or root feeding arthropod herbivores have been particularly well studied in the laboratory. Moreover, several genes and biochemical pathways responsible for the production of the emitted volatiles have been elucidated and described. These advances in understanding the volatile emissions and their ecological significance open up novel ways to modify plant volatile blends in order to enhance their attractiveness to natural enemies. Based on our experience, we present here an overview of the most promising results in manipulating the emission of specific volatile compounds, while simultaneously enhancing the responsiveness of natural enemies to particular compounds to enhance biological control of belowground herbivores of maize. However, such manipulative strategies require great caution and we emphasize the importance of taking a holistic ecological approach and to precisely evaluate risks and benefits of modifying volatile blends in the context of pest management.

Relative importance of host-derived and plant-derived volatiles in the attraction of the larval parasitoids *Cotesia marginiventris* and *Microplitis rufiventris*

Cristina Tamo[1], Matthias Held[2], Ted Turlings[3]

[1]Institute of Plant Sciences University of Bern, Switzerland, [2]Institute of Biology University of Neuchatel, Switzerland, [3]Institute of Biology University of Neuchatel, Switzerland

By utilizing a six-arm olfactometer, we compared the responses of the two larval endoparasitoids, Cotesia marginiventris and Microplitis rufiventris, to the odors of maize plants that were induced to emit volatiles. Naive wasps and wasps that had had an previous oviposition experience on an host-damaged maize plant were offered the choice between undamaged maize plants, undamaged plants treated with caterpillar regurgitant, freshly damaged plants (scratched and treated with caterpillar regurgitant), plants with the same but older damage, plants with old and a fresh damage and plants actively fed on by herbivores. The results revealed that naive C. marginiventris are highly responsive to freshly damaged plants (which typically release green leafy volatiles) and become more responsive to plants with older damage that release specific herbivore-induced volatiles after experience. In contrast, naive M. rufiventris respond best to the complete blend of plant-produced volatiles, while experience rendered this wasp more responsive to volatiles that are directly associated with the herbivores and/or their by-products. Although both wasps have similar host plant ranges, they clearly employ different strategies to find their hosts.

Behavior and Chemical Ecology

Effects of inter- and intra-specific plant volatile interactions on aphids and ladybirds

Velemir Ninkovic[1], Inger Ahman[2], Iris Dahlin[3], Martin kellner[4], Robert Glinwood[5]

[1]Swedis University of Agricultural Sciences, Sweden, [2]Swedis University of Agricultural Sciences, Sweden, [3]Swedis University of Agricultural Sciences, Sweden, [4]Swedis University of Agricultural Sciences, Sweden, [5]Swedis University of Agricultural Sciences, Sweden

In recent years it has become more and more apparent that chemical interactions between undamaged plants are very complex and highly dependent on genotype and species. These chemical interactions are expressed via volatile substances and have affects across three trophic levels; they affect barley biomass allocation, aphid settling responses and searching behaviour of predatory ladybirds. However, the effects of plant volatile communication on aphids and ladybirds depend both on the volatile emitter and receiver. Interspecific interactions between barley and certain weed species have also been found to be species dependent. In a recent study it was found that older barley cultivars were generally better volatile receivers while younger barley cultivars were more likely to provoke a response in other cultivars. Although certain cultivars respond to volatiles from other cultivars more frequently than others, the responses are specific to certain cultivar combinations. This indicates that the interaction between the emitting and receiving cultivar works in a key-lock fashion and the exact dynamics of this interplay are still to be discovered. The results stimulate discussion on plant responses to their environment as an advanced capacity of a plant to adapt to current conditions. It may be hypothesized that herbivores closely adapted to plant physiology are more sensitive to plant responses to volatiles, and that the third trophic level (predators of herbivores) respond to traits in the host plant that are shared with stress conditions

Identification of volatile compounds emitted by *Artemisia ordosica* and changes due to mechanical damage and weevil-infestation

Hui Zhang[1], Shixiang Zong[2]

[1]*Beijing Forestry University, China,* [2]*Beijing Forestry University, China*

Volatiles emitted by healthy, mechanically damaged and weevil-infested Artemisia ordosica were obtained through dynamic headspace method and analysed by automatic thermal desorption-gas chromatography-mass spectrometry (ATD-GC-MS). Twenty-eight compounds in all were identified and the qualitative as well as quantitative differences were compared. The green leaf volatiles 2-hexenal, (Z)-3-hexen-1-ol, 2-hexen-1-ol, 1-hexanol and (Z)-3-hexen-1-ol, acetate were present in all of the damaged plants, but in relatively lower proportions when plants infested by weevil Adosopius sp.; while terpenoids α-copaene, β-cedrene, (E, E)-α-farnesene and esters methyl salicylate were only present in weevil-damaged plants. The volatiles from healthy and weevil-infested leaves were dominated by D-limonene, whereas mechanical damages emitted β-pinene as the dominant compound.

Inducible responses to herbivory affect diamondback moth oviposition patterns and negatively affect larval predation.

Michael John Furlong[1], Rehan Silva[2]
[1]*University of Queensland, Australia,* [2]*University of Queensland, Australia*

Neonate diamondback moth, Plutella xylostella L (Lepidoptera: Plutellidae), larvae feed on leaves young of their Brassicaceous host plants. Within intact cabbage (Brassica oleracea L. Capitata, cv. sugarloaf) plants eggs are preferentially laid on the lower plant parts but in herbivore-damaged plants eggs are preferentially laid on the upper leaves, close to larval feeding sites. However, within Chinese cabbage (Brassica rapa L. Pekinensis, cv. Wombok) plants eggs are preferentially laid on upper leaves in both intact and herbivore-damaged plants, although intact leaves are preferred over herbivore-damaged leaves. The effects of these responses on the susceptibility of larvae to predation on cabbage plants were tested in laboratory and field studies. In the laboratory, larvae hatching from eggs laid on the lower leaves of non-induced cabbage plants took longer to establish feeding sites and were significantly more susceptible to predation than larvae hatching from eggs laid close to larval feeding sites on herbivore-induced plants. This indicates that inducible responses to herbivory can increase herbivore survival in the presence of predators. In field studies predators caused significant larval mortality but oviposition site did not affect neonate survival. However, oviposition site did affect diamondback moth survival during periods of heavy rainfall and survival rates were greater when eggs were laid on the lower leaves of non-induced plants. The study demonstrates the complex interactions between the herbivore, its host plants and its natural enemies and provides a basis from which we can begin to understand observed inter- and intra-plant distributions of diamondback moth in Brassica crops.

The chemical heterogeneity of plant defence is exploited by insects to avoid harm and find safe havens

Bronwen W. Cribb[1], Lynda E. Perkins[2], Philip B. Brewer[3], Jim Hanan[4], Myron P. Zalucki[5]

[1]The University of Queensland, Australia, [2]The University of Queensland, Australia, [3]The University of Queensland, Australia, [4]The University of Queensland, Australia, [5]University of Queensland, Australia

Insects are sophisticated animals and many have evolved physiological adaptations that negate induced plant defenses. Plants have evolved sensitive ways to detect herbivores, and interrelated strategies to defend themselves. Insect herbivory induces synthesis of the phytohormone jasmonic acid, which activates downstream metabolic pathways for various biochemical defenses such as toxins and digestion inhibitors. By visualizing jasmonic acid-responsive gene expression within whole plants, we have uncovered short-term limits to the systemic spread of plant chemical defense. By carefully tracking these, along with insect movement, we have found there are plant-wide signals early in the induction process that allow insects to detect the heterogeneity of plant chemical defences. Vulnerable insects can use these signals to move around the plant, avoiding localised sites of induction and staying ahead of induced toxic metabolites. Avoiding induced tissue in this way would provide time for insect physiological adaptations to defensive metabolites to develop. Previously, we have found that 1st instar H. armigera spend less time feeding and more time moving than 3rd instars, but despite this, 1st instars have a higher relative growth rate. Behavioural resistance to induced defenses would be expected to benefit physiologically-vulnerable insects more than those accustomed to the changed conditions. Hence, it seems likely that, as physiological adaption develops along with aging of the larvae, younger instars would be the most likely to evolve behaviour in response to induced plant defense.

Using transgenic Arabidopsis plants containing a luciferase reporter gene to map the spatial and temporal expression of genes involved in plant defence against herbivory.

Lynda Perkins[1], Bronwen Cribb[2], Philip Brewer[3], Jim Hanan[4], Myron P. Zalucki[5]

[1]The University of Queensland, Australia, [2]The University of Queensland, Australia, [3]The University of Queensland, Australia, [4]The University of Queensland, Australia, [5]University of Queensland, Australia

Plants have evolved sensitive ways to detect herbivores, and interrelated strategies to defend themselves. Insect herbivory induces synthesis of the phytohormone jasmonic acid, which activates downstream metabolic pathways for various biochemical defences such as toxins and digestion inhibitors. A limited number of genes involved in induced defence pathways of the model plant Arabidopsis have been identified. We have used transgenic Arabidopsis containing the gene for firefly luciferase (Luc) as a reporter fused to promoters of defence genes of interest to study the spatial and temporal pattern of defensive gene expression in plants. Luciferase catalyses a bioluminescent reaction and is a sensitive reporter gene for the real-time, non-invasive imaging of gene expression in planta using photon-counting cameras. Success using this technique requires careful attention to technical aspects such as penetration and pre-equilibration of the substrate luciferin into plant tissue. We have visualised the defence response in plants elicited by the application of methyl jasmonate, and by herbivory of a generalist- and specialist- feeding insect. We have uncovered short-term limits to the spread of defensive gene expression from the site of elicitation, but also systemic expression of induced genes in the longer term. To date we have studied plant response to limited herbivory, i.e. one to a few feeding bouts. Overall, the pattern of expression in response to this limited elicitation is one of spatial patchiness and temporal transience resulting in a heterogeneously defended plant at any given point in time. Currently we are investigating plant defence in response to extended herbivory.

Behavior and Chemical Ecology

Salicylic acid signaling plays an important role in mediating indirect plant defense against whitefly

Peng-jun Zhang[1], Yao-bin Lu[2]

[1]*Zhejiang Academy of Agricultural Sciences, China,* [2]*Zhejiang Academy of Agricultural Sciences, China*

Herbivore attack is known to induce indirect plant defense by releasing of volatile compounds that attract natural enemies of the herbivore. However, little is understood about the underlying mechanisms involved in indirect defense induced by the phloem-feeding insect, such as whitefly and aphid. Here, we investigate the indirect plant defense of Arabidopsis thaliana against the whitefly Bemisia tabaci, i.e. the attraction of the parasitoid wasp Encarsia formosa, as well as involved signal-transduction pathway. Parasitoids E. formosa were significantly attracted by the odors emitted from wild-type (WT) plants infested with B. tabaci compared to uninfested WT plants. This attraction is shown to result from the enhancement in ?-myrcene emission from WT plants infested with B. tabaci. Exogenous salicylic acid (SA) application also led to the attraction of parasitoids, but not exogenous jasmonic acid (JA). Remarkably, the attraction of parasitoids still occurred in uninfested SA-elevated (cpr-6), infested JA-deficient (dde2-2), infested ethylene-insensitive (ein2-1) mutants, but not in infested SA-defective mutants (NahG and npr-1). Taken together, we conclude that the SA signaling pathway plays a key role in mediating whitefly-induced indirect plant defense.

Effects of tomato plants responses induced by *Frankliniella occidentalis* on the behavioural response and host preference of *Bemisia tabaci*

Yaobin Lu[1], Xiaoxing Li[2], Weidi Li[3], Pengjun Zhang[4]

[1]Zhejiang Academy of Agricultural Science, China, [2]Zhejiang Academy of Agricultural Science, China, [3]Zhejiang Academy of Agricultural Science, China, [4]Zhejiang Academy of Agricultural Science, China

The differences of the host preference and behavioural responses of B. tabaci on different treatments (undamaged plants (CK) vs plants damaged by B. tabaci (B); undamaged plants (CK) vs plants damaged by the F. occidentali (F); plants damaged by B. tabaci plants(B) vs damaged by B. tabaci and F. occidentalis (B+F)), were studied with the methods of Y-tube olfactometer and choice test. And the differences of the volatiles of different treatments were analyzed by GC-MS. The behavioural responses of female adult B. tabaci to different treatments in CK vs B and CK vs F treatment combinations were not significantly respectively. But in B vs B+F treatment combination, the female adult B. tabaci were attracted to the plant damaged by the B. tabaci. In the choice test of CK vs B and CK vs F, the adult B. tabaci prefered to feed and oviposit on the plant undamaged and in B vs B+F, the adult B. tabaci prefered the plant damaged only by B. tabaci and also prefered to oviposit on it. Furtherly, the analysis of the volatiles of different treatments showed that Comparing to the host plant damaged by B. tabaci, the amount of β-myrcene which shows strong attractableness to B.tabaci, reduced significantly and the amount of β-phellandrene which shows repellence to B. tabaci, increased significant in the plants damaged by both herbivores. Taken together, the plant responses induced by F. occidentalis have a great effect upon the host preference and behavioural responses of B. tabaci.

Soil microbial community and plant-insect interactions

Kiran Ramesh Gadhave[1], Alan C. Gange[2]
[1]*University of London, United Kingdom,* [2]*University of London, United Kingdom*

The soil microbial community may have a profound effect on the biochemical, physiological and morphological aspects of plants. Plant Growth Promoting Rhizobacteria (PGPRs) and Arbuscular Mycorrhizal Fungi (AMF) are important components of soil microbial community that are being commercially exploited for plant growth promotion, biological control and induction of plant systemic resistance against diverse pathogens. However, their role as biological pest control agents remains virtually unexplored. The aim of this study is to determine whether soil microbial community affects herbivore attack above ground. Experiments will be presented in which the effects of different soil microbial enhancement methods are tested on several crops and the consequences for above ground insects determined.

Whitefly infestation elicits defense responses against bacterial pathogens on the leaf and root and belowground dynamic change of microflora in pepper

Choong-Min Ryu
Korea Research Institute of Bioscience and Biotechnology, Republic of Korea

Plants have evolved general and specific defense mechanisms to protect themselves from diverse enemies, including herbivores and pathogens. To maintain fitness in the presence of enemies, plant defense mechanisms are aimed at inducing systemic resistance: in response to the attack of pathogens or herbivores, plants initiate extensive changes in gene expression to activate "systemic acquired resistance" against pathogens and "indirect defense" against herbivores. Recent our work revealed that leaf infestation by whiteflies, stimulated systemic defenses against both an airborne pathogen and a soil-borne pathogen, which was confirmed by the detection of the systemic expression of pathogenesis-related genes in response to salicylic acid and jasmonic acid-signaling pathway activation. Further investigation revealed that plants use self-protection mechanisms against subsequent herbivore attacks by recruiting beneficial microorganisms called plant growth-promoting rhizobacteria/fungi, which are capable of reducing whitefly populations. Our results provide new evidence that plant-mediated aboveground to belowground communication and vice versa are more common than expected.

Behavior and Chemical Ecology

The chemical ecology involved in cuckoo bumblebee offspring survival in host nest

Patrick Pierre Lhomme[1], Manfred Ayasse[2], Irena Valterova[3], Pierre Rasmont[4]

[1]University of Mons, Belgium, [2]Insitute of experimental ecology, Germany, [3]IOCB, Academy of Sciences, Czech Republic, [4]University of Mons, Belgium

In social insects, the high energetic costs of brood care have promoted the evolution of social parasites that exploit worker force of conspecifics or heterospecifics. In bumblebees, all the species of the subgenus Psithyrus have lost their worker caste and are completely dependent on host workers to produce their offspring. One of the most striking challenges for these social parasites is to avoid the detection and aggression by their hosts. Many studies have shown how socially parasitic queens overcome host recognition systems to enter successfully into host colonies. However, once a social parasite has successfully usurped a host nest, its emerging offspring still face the same challenge of avoiding host recognition. This is especially the case for the young Psithyrus males who possess a strong chemical signature because of their early production of species specific sex pheromones. Therefore, host workers might be able to recognize them. We hypothesized that parasitic males should require a strategy to prevent host agonistic behaviors. This study presents how males of the cuckoo bumblebee Bombus vestalis fool Bombus terrestris workers during their intranidal life. Our results show that parasitic males produce an allomone that repel attacking host workers. This is the first example of an active exfiltration strategy in social parasites.

Feeding and oviposition preference of *Frankliniella occidentalis* for crop and weed species commonly occurring in French bean fields in Kenya

Johnson Ounya Nyasani[1], Rainer Meyhofer[2], Subramanian Sevgan[3], Hans-Michael Poehling[4]

[1]Kenya Agricultural Research Institute, Kenya, [2]Leibniz Universitat Hannover Herrenhauser Strasse , Germany, [3]International Centre of Insect Physiology and Ecology, Kenya, [4]Leibniz Universitat Hannover Herrenhauser Strasse, Germany

Western flower thrips (WFT), Frankliniella occidentalis (Pergande) (Thysanoptera: Thripidae), is an important pest of French beans in Kenya. However, information on the feeding activity and oviposition preference of WFT on crop and weed hosts associated with French beans in Kenya is lacking. To determine the feeding and oviposition preference of WFT for crop and weed plants commonly encountered in French bean fields in Kenya, no-choice and choice experiments were conducted using four important crop and weed plants. Among the crop plants tested, highest feeding and oviposition activity of WFT was recorded on courgette/zucchini (Cucurbita pepo L.) and French beans (Phaseolus vulgaris L.). Spinach beet (Beta vulgaris L.) and sweet pepper (Capsicum annuum L.), were of minor importance for feeding and oviposition. Among the weeds tested, gallant soldier (Galinsoga parviflora Cav.) was the most preferred host plant for feeding and oviposition compared to Chinese lantern (Nicandra physaloides L.), wild crucifer (Erucastrum arabicum Fisch. & C.A. Mey.) and pigweed (Amaranthus hybridus L.). Nevertheless Phaseolus vulgaris was the most preferred host for feeding and oviposition in presence of the weed species G. parviflora, E. arabicum and A. hybridus. A positive correlation between the number of feeding punctures and the number of eggs oviposited by WFT on crop and weed plants was observed. The results of this study show that P. vulgaris, C. pepo and G. parviflora are both good feeding and oviposition hosts of WFT. Cucurbita pepo and G. parviflora may serve as potential sources of WFT outbreaks within French bean fields.

Responses of *Riptortus pedestris* (Hemiptera: Alydidae) to host food and of *Apolygus spinolae* (Hemiptera: Miridae) to host volatiles

Eugene Lim[1], Hyun Sik Roh[2], Chung Gyoo Park[3]

[1]Gyeongsang National University, Republic of Korea, [2]Gyeongsang National University, Republic of Korea, [3]Gyeongsang National University, Republic of Korea

For many insect species, host plant plays an important role on their communications, and thus on the formation of feeding and mating aggregations, on insect strategies to locate both hosts and mates. Two different types of hosts, sweet (non-astringent) persimmon and soybean, can affect the pheromone production and reproduction of Riptortus pedestris male and female, respectively. Male adults fed on soybean produced all kinds of pheromone components, (E)-2-hexenyl (Z)-3-hexenoate, (E)-2-hexenyl-(E)-2-hexenoate, tetradecyl isobutyrate, and octadecyl isobutyrate. Female adults fed on soybean could normally lay eggs. However, males fed on sweet persimmon did not produce octadecyl isobutyrate and especially, tetradecyl isobutyrate which was known as a key functional component of its pheromone. No females fed on sweet persimmon could lay eggs. This finding indicates that host resources greatly affect the chemical communication and reproduction of R. pedestris. The green pale plant bug, Apolygus spinolae, has been known as a grape, sweet persimmon and green tea pest feeding on young leaves. Responses of the plant bug were tested to the several compounds emitted from green tea leaf, grape vine, and from the plant bug itself, using electroantennogram (EAG) and in the fields. EAG responses of A. spinolae female adults were recorded using 11 volatile compounds. Field attractiveness tests for both female and male were done using two more compounds in 2010 and 2011. Through these experiments, two compounds, methyl salicylate and tridecane were selected as possible attractants for A. spinolae.

Study on maize pollen volatile compounds as potential attractant to blood fed and unfed female *An. arabiensis* under laboratory

Betelehem Wondwosen Hailu[1], Emiru Seyoum[2], Rickard Ignell[3], Sharon Hill[4]

[1]Addis Ababa University, Ethiopia, [2]Swedish Agricultural University, Ethiopia, [3]Swedish Agricultural University, Sweden, [4]Swedish Agricultural University, Sweden

This study on main Ethiopian vector of malaria, Anopheles arabiensis was designed to identify potential attractant volatile compounds from two differentially attractive strains of maize pollen, BH-660 (Bako Hybrid-660) and ZM-521 (Melkassa 2). The behavioral responses demonstrated by blood fed and non-blood fed adult female An. arabiensis to pollen and extracts from BH-660 and ZM-521 illustrated olfactory mediated attraction to both strains of maize pollen. The An. arabiensis were attracted to pollen and extracts from both strains differently: blood fed mosquitoes were attracted to lower doses of BH-660 than to ZM-521 volatile for extracts and pollens; whereas unfed females were attracted to lower doses of ZM-521 than to BH660 maize pollen and odor extracts. In the same line, the pollen and extracts of BH-660 maize were more attractant than the other maize va ZM-521 maize variety. Importantly, the outcome of the study implies that olfactory cues were the driving external factor that assisted both blood fed and non-blood fed An. arabiensis to inhabit areas near BH-660 and ZM-521 maize pollen.

Attraction of female *Anopheles stephensi* mosquitoes to the spores of entomopathogenic and non-entomopathogenic fungi

Thomas Baker[1], Justin George[2], Simon Blanford[3], Nina Jenkins[4], Matthew Thomas[5]

[1]Penn State University, U.S.A., [2]Penn State University, U.S.A., [3]Penn State University, U.S.A., [4]Penn State University, U.S.A., [5]Penn State University, U.S.A.

We performed behavioral Y-tube olfactometer assays in the laboratory to test the upwind flight responses of the mosquito, Anopheles stephensi a major vector of human malaria in Asia, toward the fungal spores of two entomopathogenic species, Beauveria bassiana and Metarhizium acridum. Our group has been working toward the goal of applying spores to various indoor surfaces of dwellings as a biopesticide. Unfed female An. stephensi mosquitoes were tested one-at-a-time for their upwind flight propensity toward the arm of the Y-tube that contained a 50 mg loading of spores, versus the other arm that contained a blank filter paper. The females clearly exhibited a strong attraction towards B. bassiana spores; 75% of the females tested flew upwind to within 1 cm of the spores, and a significant percentage of these actually landed on the spores themselves. A high percentage of the mosquitoes (70%) was likewise attracted to 50 mg of the spores of M. acridum, and also to a lesser degree (65%) to 50 mg of the spores of Aspergilus spp., a non-entomopathogenic species. The spores of Penicilium spp., on the other hand, were deterrent to An. stephensi females, 80% of which preferred to fly up the blank arm of the Y-tube olfactometer and not to the Penicilium spores. In competitive choice-tests between the spores of different fungal species, those of B. bassiana were preferred, with 67%, 67% and 82% flying upwind to these spores vs. those of M. acridum, Aspergillus spp and Penicillium spp , respectively.

GC-EAD analyses of phytophagous insects to volatiles from different host plants

Li Chen
Institute of Zoology, the Chinese Academy of Sciences, China

The differences in chemical profiles of volatiles, especially those semiochemicals detected by insect antennae, are predicted to play important roles in mediating host preference of phytophagous insects. To test the above protection, two model systems were utilized for investigation of plant volatiles involved in host preference. The first one includes the giant swallowtail butterfly, Papilio cresphontes (Lepidoptera: Papilionidae), and its two key host plants, Zanthoxylum clava-herculis, and Ptelea trifoliata, and a non-preferred host plant, Sassafras albidum. The second one includes the long-legged chafer, Hoplia spectabilis, a preferred host plant, Hippophae neurocarpa, and two non-preferred host plants, Myricaria germanica, Potentilla fruticosa. Preliminary GC-EAD tests with P. cresphontes revealed four components each from Z. clava-herculis and P. trifoliata (three peaks common to both extracts) and seven from S. albidum (one shared with Z. clava-herculis) which elicited GC-EAD activity in P. cresphontes females. GC-EAD tests H. spectabilis revealed that at least ten components from the three plants elicited GC-EAD activity in both sexes of H. spectabilis, which were identified as trans-2-hexenal, cis-3-hexenylacetate, cis-3-hexenol, nonanal, decanal, (E,Z)-2,6-nonadienal, citral, methyl salicylate, benzylalcohol, phenol, eugenol. The first four components and an unidentified component in trace amount were shared by all three host plants. Plant derived volatile compounds shared by the tested plants may be utilized by herbivores for host plant selection. Future studies will include examination of non-host plant species by GC-EAD and GC?MS analyses to compare active components among various host plants that may contribute to host-plant preference.

Olfactory receptor neurons and host specificity in phytophagous insects

Kye Chung Park
Plant & Food Research, New Zealand

Phytophagous insects use olfactory information to locate their host plants. Therefore, their olfactory sensory system is directly related to the volatile emanations of their host plants. Here we show the relationship between the response profiles of olfactory receptor neurons (ORNs) and the profiles of volatile compounds of host and non-host plants in two weevil and four moth species. We identified ORNs in the weevils Sitona lepidus and S. discoideus and the moths Cydia pomonella, C. succedana, Epiphyas postvittana and Uraba lugens, by using single sensillum recording technique. Each species shows distinct species-specific set of ORN populations each of which has unique response spectrum to specific range of plant volatile compounds. The plant-volatile sensitive ORN populations could be classified into either agonist or antagonist, depending on their responsiveness and the presence of their active compounds in the host and non-host plants. We hypothesize that the phytophagous insects use combinational sensory input of both agonist and antagonist ORNs for locating their host plants, and the presence of antagonist ORNs enhance the discriminating ability between host and non-host plants. Based on this, it would be possible to predict the range of host plants for invasive insect species by comparing their ORN profiles and the chemical profiles of volatile emanations of plants. Identifying agonist and antagonist ORNs can also provide critical information in developing attractants and repellents.

Response of female *Bactocera papayae* (Diptera: Tephritidae) on five mango varieties

Agus Susanto Suryana
Universitas Padjadjaran, Indonesia

Fruit fly is one of key pest on fruits, the damage on fruits can reach 100%. The objective of this research was to study the respons of female B. papayae on 5 mangoes varieties. Tests conducted on five varieties of mango (Gedong, Arumanis, Cengkir, Bapang and TO) at different levels of maturity of mango (young fruit, mature / ripe and full ripe) using a modified Olfaktometer tube. Each treatment is infested of 50 female fruit flies are placed in the middle of the tube. At each end of the Olfaktometer tube is placed one variety of mango. Observation was done on the attractiveness of fruit fly oviposition sites compare with the different character of each mango varieties. Response of B. papayae on the mango varieties, indicating that the fully ripe mangoes more chosen by female fruit flies (83.6%), ripe mango (52%) and young mango (32.4%). Morphological characters of the full ripe mango, has a soft exopericarp and high sugar levels. Gedong varieties more chosen by female fruit flies for oviposition, compared with other varieties. Strong scent of varieties gedong, became one of the factors that influence the choice of emission levels, of volatile compounds released by the varieties Gedong allegedly more powerful than the other varieties. The results of regression analysis and correlation, suggesting that the aroma was positively correlated and have significant influence in the selection of the host. This suggests that the aroma plays an important role in the selection of the host.

Behavior and Chemical Ecology

Fatty acid amino acid conjugates diversification in lepidopteran caterpillars and physiological adaptation found in plants to the FACs.

Naoki Mori[1], Naoko Yoshinaga[2]

[1]Kyoto University, Japan, [2]Kyoto University, Japan

Fatty acid-amino acid conjugates (FACs), first identified from beet armyworm Spodoptera exigua larvae (Alborn et al., 1997), have been found in noctuid as well as sphingid caterpillar oral secretions and especially volicitin [N-(17-hydroxylinolenoyl)-L-glutamine, 17OH-volicitn] and its biochemical precursor, N-linolenoyl-L-glutamine, are known elicitors of induced volatile emissions in corn plants. We conducted FAC screening of 29 lepidopteran species and found FACs in 19 of these species (Yoshinaga et al., 2010). Thus, FACs are quite commonly synthesized through a broad range of lepidopteran caterpillars. Recently, we have newly identified N-(18-hydroxylinolenoyl)-L-glutamine (18OH-volicitin) from Manduca sexta regurgitants and showed that 18OH-volicitin was no more active than N-linolenoyl-L-glutamine in corn seedlings while 18OH-volicitin was as active as 17OH-volicitin when treated on solanaceous plants such as tobacco or egg plants, host plants of M. sexta. Meanwhile, these glutamine type FACs including 18OH-volicitin are infinitesimal components in M. sexta. Instead the larvae synthesize large amounts of glutamic acid type FACs as main components, which show half of the activity in corn plants and the almost same activity in egg plants. These results suggest that plants have developed the defense system customized to their pest insects.

Behavior and Chemical Ecology

Gall aphids manipulate plant volatiles for defence against vertebrates

Michael Rostas[1], Moshe Inbar[2]

[1]Lincoln University, New Zealand, [2]University of Haifa, Israel

Gall-forming insects manipulate the structure and function of their host plant to gain protection and better nutrition. Since gall traits are controlled by the insect, galls are considered as their extended phenotype. Little is known about the metabolism and function of plant volatiles in galls. Around the Mediterranean, several aphid species (Fordinae) induce typical galls on Pistacia spp trees. Field observations suggested that natural enemies, such as birds, goats and herbivorous insects are deterred by the galls. The aphid Slavum wertheimae induces conspicuous large, cauliflower-shaped galls on the lateral buds of P. atlantica trees. We hypothesized that gall volatiles may act as warning (deterring) signals. Comparative analyses of defensive secondary metabolites revealed that, compared with leaves and fruits, the galls are heavily protected with higher levels of tannins, mono- and sesquiterpenes. Furthermore, galls released large amounts of volatile terpenes, which increased by 80% following mechanical damage. In bioassays we found that galls are indeed unpalatable and that scent is sufficient to deter both goats and birds; suggesting a signaling role for volatiles in the gall's headspace. We conclude that the aphids are well protected by the secondary metabolites in the galled tissue while volatiles serve in the front line of gall (insect) defenses. Volatiles in the headspace of galls are the external expression of the aphid's extended phenotype.

Non-host volatiles to control bark beetles - A new forest protection method under development

Carl Rikard Unelius
Linnaeus University Kalmar, Sweden

After storm events there is a need to protect the forest. Storm felling creates fresh stand edges with trees stressed due to the quick change of environmental conditions (e.g. sun exposure) and thereby susceptibility for bark beetle attack. Newly exposed stand-edges are in need of stabilisation against the outbreak of bark beetles that inevitable will occur in the years after a big storm. In recent years attempts have been made to use natural non-host volatiles (NHV) from broad-leafed trees to protect conifer trees against bark beetles. In this talk recent advances in the development of this method will be presented with the focus on Ips typographus.

Delivering robust semiochemical based crop protection via the seed

John Anthony Pickett
Rothamsted Research, United Kingdom

Use of chemical ecological tools in crop protection is still considered by many practitioners, in both agriculture and the agricultural chemical industry, to be an inefficient option. However, pressure for sustainable crop protection without recourse to seasonal inputs reliant upon high carbon footprint, at least for delivery, requires us to look more diligently at approaches delivered by the seed. Breeding, even with new molecular approaches, and the first generation of genetically modified (GM) crops offer only limited solutions for pest control, still leaves synthetic chemical eradicant pesticides as the preferred option. Many of the latter compounds have been developed from natural product leads and, indeed, some are themselves natural and produced commercially by fermentor technologies. This means that the genetics associated with their biosynthesis can be elucidated further for exploitation, particularly for a new generation of GM crops. Most crops contain defence biosynthetic pathways which can, with recent developments in plant molecular genetics, be improved by novel breeding strategies, as well as by GM. By extending chemical ecological tools from metabolites acting directly on the physiological processes of pests, diseases and weeds, we can also consider targets that regulate development by acting as semiochemicals, including pheromones. Examples of all these approaches will be provided and discussed in the light of new opportunities from use of small lipophilic plant-derived compounds acting as elicitors of defence.

Impacts of microbial associations on plant-insect

Consuelo M De Moraes
PSU, United States Minor Outlying Islands

Plants inhabit complex environments in which they simultaneously interact with a diverse array of other species. Interactions with microbial pathogens and other symbionts can entail significant changes in plant chemistry that in turn affect interactions with insects, including disease vectors and non-vector herbivores. Recently we have been examining how a number of plant pathogens (e.g., viruses and bacteria) and mutualists (rhizobia) influence plant-insect interactions mediated by plant nutritional quality, defense chemistry,and volatile emissions. This work suggests that such effects can often be profound and in some cases can influence plant-insect interactions in ways that suit the interests of the microbial partners. For example, pathogen transmission mechanisms appear to be an important factor shaping the evolution of effects on host-vector interactions. I will present results from our most recent work and discuss implications for the chemical ecology of complex ecological communities.

Airborne interactions between different plant cultivars- Effects on aphids and their natural enemies

Robert Glinwood
Swedish University of Agricultural Sciences, Sweden

Plants damaged by herbivores or pathogens release volatiles active in defense signaling between or within plants, but undamaged plants may also engage in chemical interactions. We present results that contribute new perspectives on allelopathy and use of volatile cues by plants and insects. In a system consisting of different plant species and different barley genotypes we show that airborne signaling reduces attractiveness to an insect herbivore and affects interactions with the herbivore's predators. In barley, the inducing and responding capacity is shown to be genotype-related. Volatile profiling shows differences in the volatile blends released by different barley genotypes. Increased understanding of chemical interaction between undamaged plants may give a new outlook on the ecology of mixed genotype cropping and weed-crop interactions and their role in sustainable crop production.

Attract to kill: enhancing effectiveness of mobile and immobile biological control agents

Marcel Dicke
Wageningen University , Netherlands

Biological control of arthropod pests is a durable method that is extensively used worldwide. Natural enemies of arthropod pests are used to keep the pest population below the economic injury level. Biological control agents include predators, parasitoids, viruses, bacteria and nematodes. Many effective natural enemies are able to find individuals of the pest species at low densities. This may involve the use of chemical cues originating from the pest or its food. Also arthropod pests exploit chemical cues to find their food including our crops and our animals. In order to enhance biological control we may exploit the involvement of chemical cues in the biology of pests and their natural enemies. We may devise methods to enhance the location of a pest by its natural enemy or to attract the pest to a site where we apply a natural enemy that does not actively locate its victim. Examples for predatory arthropods and for entomopathogenic fungi will be provided, including options to exploit chemical ecological knowledge in pest control.

Exploiting chemical ecology of insect-plant and plant-plant interactions in developing novel IPM strategies for Africa

Zeyaur Khan[1], Charles Midega[2], Toby Bruce[3], Tony Hooper[4], John Pickett[5]

[1]International Centre of Insect Physiology and Ecology (icipe), Kenya, [2]International Centre of Insect Physiology and Ecology (icipe), Kenya, [3]Rothamsted Research, United Kingdom, [4]Rothamsted Research, United Kingdom, [5]Rothamsted Research, United Kingdom

Development of a novel push-pull approach for integrated pest and weed management is described. Appropriate plants were discovered that naturally emit signaling chemicals (semiochemicals) that influence insect-plant interactions. Plants highly attractive for egg laying by stemborer pests were selected and employed as trap crops (pull), to draw pests away from the main crop. Of these, Napier grass, Pennisetum purpureum (Schumach), despite its attractiveness, supported minimal survival of the pests' immature stages. Plants that repelled stemborer pests, notably molasses grass, Melinis minutiflora P. Beauv., and forage legumes in the genus Desmodium, were selected as intercrops (push), which also attracted natural enemies of the pests. Desmodium intercrops suppressed parasitic weed, Striga hermonthica (Del.) Benth., through an allelopathic mechanism. Desmodium root exudates contain novel flavonoid compounds, which stimulate suicidal germination of S. hermonthica seeds and dramatically inhibit its attachment to host roots. The companion crops provide valuable forage for farm animals while the leguminous intercrops also improve soil fertility and moisture retention. The system is appropriate as it is based on locally available plants, not expensive external inputs, and fits well with traditional mixed cropping systems in Africa. To date it has been adopted by more than 47,000 smallholder farmers in East Africa where maize yields have increased from ~1?t ha?1 to 3.5?t ha?1. Opportunities for semiochemical delivery by companion plants, including plant-plant signaling and early herbivory alert, are being explored for developing future smart IPM strategies for Africa.

New frontiers for manipulation of beneficial insects in crop protection: From chemical to multimodal communication.

Miguel Borges[1], Raul Alberto Laumann[2], Maria Carolina Blassioli-Moraes[3]
[1]Embrapa - Brazil, Brazil, [2]Embrapa - Brazil, Brazil, [3]Embrapa - Brazil, Brazil

Achieving Food and Environmental security is recognized as one of the main directions of research in biological and agronomical sciences over the next few decades. New approaches to minimize the use of pesticides and improve the quality and productivity of food is crucial. Two tools have been proposed to minimize insecticide application on arable crops: (i) the use of semiochemicals from plants and insects and (ii) natural enemies. Soybean is one of the most important cultures in Brazil and stink bugs are the principal pests all around the country. They have been partially controlled by egg parasitoids (Platygastridae) through inundative release. However, this approach has limitations because it is laborious and costly. An alternative approach could be the use of semiochemicals to behavioural manipulation of natural enemies for conservative biological control strategies. Platygastridae wasps to locate their host use either herbivore-induced plant volatiles, herbivore-defensive compounds, sex pheromones and other host producer cues, vibratory signals for instance, to find their host. Another alternative is the manipulation of plant volatiles by breeding, metabolic engineering or exogenous application of naturally-occurring elicitors of plant defence to manage parasitoids. Notwithstanding, the dosage, time of application, and other aspects need to be improved before extensive use of this strategy in soybean crops. The integrated use of semiochemicals with other cues could help to develop more efficient tools for this behavioural manipulation. We intend to present results about the multimodal communication of Platygastridae egg parasitoid wasps, and discuss future steps required prior to application in agriculture.

Sex pheromones of mirid bugs: Old problems and new solutions

David Robert Hall[1], Jerry V Cross[2], Michelle Fountain[3], Joe Sarfo[4], Colin Campbell[5]

[1]University of Greenwich, United Kingdom, [2]East Malling Research, United Kingdom, [3]East Malling Research, United Kingdom, [4]Cocoa Research Institute of Ghana, Ghana, [5]University of Greenwich, United Kingdom

Mirid bugs are important pests of many crops world-wide. They have been a rich source of new compounds for chemical ecologists, but establishment of behavioural roles for the compounds and application in management of pest species have been less rewarding. Most mirid bugs have metathoracic glands producing compounds which may function as sex pheromones, alarm pheromones and defence compounds, greatly complicating their study and application. Bugs of the sub-family Bryocorinae are unusual in not having metathoracic glands. Two species, Distantiella theobromae and Sahlbergella singularis are pests of cocoa in West Africa and share two female-produced sex pheromone components. The synthetic compounds attract males when released from standard dispensers and use of pheromone traps for monitoring and control is being investigated. Bugs of Lygus and related genera are more typical with large metathoracic glands. Over the last 30 years, several species have been shown to produce three main compounds, hexyl butyrate, (E)-2-hexenyl butyrate and (E)-4-oxo-2-hexenal, but their roles as components of sex pheromones have not been confirmed, at least in part because of the difficulty of dispensing these compounds in a specific blend over a significant period. We have studied four Lygus species and shown they produce these three compounds in characteristic ratios. Novel dispensers have been developed which release defined blends of the three components for at least one month under field conditions. When combined with suitable trap designs, good attraction of males has been demonstrated, opening the way to new approaches for management of these pests.

A first step towards the control of a major root pests: Using chemical ecology to understand why it is a pest

Ted Turlings
University of Neuchatel, Switzerland

We use a chemical ecological approach to better understand the interactions among maize plants, pest insects and the natural enemies of the pests. These efforts have led to an explanation for the voraciousness of one of the most important pests of maize, the Western corn rootworm or Diabrotoca virgifera virgifera. The larvae of this beetle cost American farmers an estimated two billion dollars annually. Since its incidental introduction into the Balkan region in the 1990s it has rapidly spread and become a serious problem in Europe as well. A series of chemical analytical experiments and feeding assays that included mutant maize plants we think we have revealed the reason why the insect is so successful on maize. The larvae were found to prefer feeding on nutritious crown roots of maize plants. These roots are essential for optimal performance of the plant and logically well-defended, mainly by toxic benzoxazinoids that normally deter herbivores from feeding on these roots. The rootworm larvae, however, are completely unaffected by the toxins and use them to identify the nutritious roots, which are rich in sugars and amino acids. This explanation for the success of D. virgifera on maize opens the way for new approaches to control this pest. We argue that in general, a good understanding of chemically mediated interactions among plants and insects is essential for the development of novel and ecologically sound strategies for crop protection.

Elucidating the chemical ecology of belowground plant-plant communication

Emilio Guerrieri[1], Pasquale Cascone[2], Luigi Iodice[3], Sarah Y. Dewhirst[4], Janet Martin[5], John A. Pickett[6], Michael A. Birkett[7]

[1]Institute for Plant Protection National Research Council of Italy, Italy, [2]Institute for Plant Protection National Research Council of Italy, Italy, [3]Institute for Plant Protection National Research Council of Italy, Italy, [4]Rothamsted Research, Harpenden, United Kingdom, [5]Rothamsted Research, United Kingdom, [6]Rothamsted Research, United Kingdom, [7]Rothamsted Research, Harpenden, UK, United Kingdom

In pioneering studies on plant-aphid interactions, we have observed that when bean plants, Vicia faba, are infested with pea aphids, Acyrthosiphon pisum, they transmit signals via the rhizosphere that induce aboveground defence in intact, neighbouring plants. In wind tunnel assays, the generalist aphid parasitoid, Aphidius ervi, is significantly attracted to intact V. faba grown in hydroponic solution previously used to grow A. pisum-infested plants. To identify the rhizosphere signal(s) which mediate belowground communication, root exudates were collected from hydroponically-grown 10 day-old A. pisum-infested and uninfested V. faba plants, and exudates subjected to reverse-phase (C18) solid-phase extraction (SPE). When SPE extracts were re-constituted in hydroponic water subsequently used to grow intact V. faba, the extract from A. pisum-infested V. faba caused intact plants to become attractive to A. ervi. Preliminary results demonstrate a role for small lipophilic molecule (SLM) chemical signals in belowground plant-plant communication following aphid colonisation. The isolation and identification of the biologically active chemical(s) via bioassay-guided HPLC fractionation is currently under way.

Elicitation of plant defence by small lipophilic molecule activators: Understanding underlying mechanisms and towards use in crop protection

Michael A Birkett
Rothamsted Research, United Kingdom

Small lipophilic molecule (SLM) activators of plant defence offer a route to sustainable crop protection, by inducing plant secondary metabolism pathways that provide either direct or indirect defence against insect pests. Although they can potentially be deployed directly as crop protection agents, the long term vision is to use activators as novel tools in the selection, and breeding, of resistant traits into new varieties and cultivars that respond rapidly to insect damage. It is envisaged that this strategy will deliver sustainable crop protection via the seed. Seminal studies on the interaction of aphids and their natural enemies, parasitoids and predators, with host plants showed that the interaction is modified by the activation of defence signalling by cis-jasmone, a volatile plant secondary metabolite. The mechanisms underlying activation of defence by cis-jasmone were studied in the model plant Arabidopsis thaliana and in wheat, Triticum aestivum, and the potential for using cis-jasmone as a practical tool for activation of defence in major world crops was explored. Stress signalling is activated in cotton, Gossypium hirsutum, and soybean, Glycine max, and is primed in maize, Zea mays. These studies demonstrate promise for the use of SLMs as natural plant activators in the sustainable control of pest aphids, stink bugs and leafhoppers. To this end, new classes of SLM activators are being investigated, including those associated with below-ground plant/plant communication in field beans, Vicia faba, following above-ground aphid herbivory, and with induction of indirect defence in maize following herbivore oviposition.

Patterns of attraction of herbivore pests to plant volatiles

Cesar Rodriguez-Saona[1], Zsofia Szendrei[2]
[1]*Rutgers University, U.S.A.,* [2]*Michigan State University, U.S.A.*

Plant volatiles play an important role in the host and mate finding behaviors of insect herbivores, and understanding the mechanisms of this process can provide tools for pest management. Here we used a meta-analysis to synthesize this knowledge and to look for patterns on the effects of plant volatiles on insect pests. Our goal was to identify herbivore and plant traits that might explain the herbivores' behavioral response to plant volatiles in field applications. We used a total of 374 unique plant volatile-insect herbivore interactions obtained from 34 published studies investigating 50 herbivore pest species in our analysis. We found that attractants, but not repellents, had a significant effect on insect herbivore abundance; this difference could be due to the smaller number of field studies that tested plant volatiles as repellents (3%). Females were significantly more attracted to plant volatiles than males. The diet breadth of herbivores was independent of a behavioral response to plant volatiles, but the effect of volatiles was the greatest on chewers, followed by wood-borers and sap-feeders. There are more demonstrations of attraction to plant volatiles in Lepidoptera than in Thysanoptera. The method of plant volatile application had a significant effect on herbivore abundance and increasing the number of chemicals in blends attracted more herbivores. The magnitude of the response of herbivores to plant volatiles in forest and agricultural habitats was similar. These data were published in 2010 (Ent. Exp. Appl. 134:201). We will highlight areas needing research in using plant volatiles to manage insect pests.

Influence of mating on responses of *Helicoverpa armigera* moths to synthetic plant volatiles

Alice Del Socorro[1], Peter Gregg[2]

[1]*University of New England, Australia,* [2]*University of New England, Australia*

Responses of mated and unmated Helicoverpa armigera female moths to various synthetic plant volatile compounds were studied using a two-choice olfactometer. Results suggest that mated moths are both more active in the olfactometer and more responsive to most compounds than unmated ones. Even in a blank olfactometer (ie, no volatile) or where only the carrier canola oil was present, there was a trend for more mated than unmated moths in the test chamber, although the differences were not statistically significant. There was also a trend for the difference between mated and unmated moths to be greater with more attractive compounds. We also compared mated females with females which had been confined with another female for an equivalent period to that which the mated females spent with males, to determine whether it was mating per se that influenced responsiveness in the olfactometer, or just confinement with another moth. There was no difference between these two groups of females, suggesting it is mating which is the crucial factor.

How fruit moths recognize host plant odors

Silvia Dorn[1], Adriana Najar-Rodriguez[2], Jaime Pinero[3]

[1]ETH Zurich, Switzerland, [2]ETH Zurich, Switzerland, [3]ETH Zurich, Switzerland

Chemically-mediated host plant selection by female herbivores may seem to be a straight-forward interaction between plants and females searching for suitable oviposition sites. However, recent advances in research on plant-herbivore relationships reveal a more complex situation with important consequences. Using the model system composed of the invasive fruit moth Grapholita (=Cydia) molesta and volatiles from its primary host peach, we addressed some key aspects of the females' olfactory response to host plant volatiles. Starting from the complex volatile blend emitted by the plant, we simplified the mixture in a stepwise manner while maintaining its attractive properties. With this top-down approach, we detected a synergistic interaction between two constituents, which are behaviorally ineffective when tested alone. Neurophysiological work confirmed this synergism conclusively. Motivated by the observation that single females respond differently to the same odor blend, we investigated the heritability of odor-guided host location behavior in this species using a full-sib/half-sib approach. Results documented a considerable genetic basis for olfactory attraction of females. Moreover, there is a genetic trade-off between female attraction and an important life history trait. This trade-off might be attributable to conflicting resource allocation, and it highlights the inherent constraint for simultaneous selection for both traits. Invited submission: Chemically-mediated host plant selection, a complex and challenging topic (6-4.)

Microbial odors mediate host finding in insect herbivores

Peter Witzgall
SLU, Sweden

Attraction of the fruit fly D. melanogaster to a blend of yeast volatiles with acetic acid as a main attractant compound (Becher et al. 2010, 2011) demonstrates the significance of yeasts in Drosophila behavioral ecology. With this in mind, we have investigated the role of yeasts for host finding and oviposition in other insect herbivores. We conclude that plant-yeast-insect interactions are more widespread than previously assumed, and that yeasts and other micro-organisms are important for our understanding of the ecology of insect herbivores and their evolutionary diversification. The traditional bi-trophic plant-insect niche concept must be updatedto accomodate for the role of micro-organisms in host-finding. This will be illustrated with results from current studies. Attacking behavior and its communication of an invasive bark beetle *Dendroctonus valens*

Zhudong Liu[1], Jianghua Sun[2]
[1]*Institute of Zoology, Chinese Academy of Sciences, China,* [2]*Institute of Zoology, Chinese Academy of Sciences, China*

The invasive red turpentine beetle, Dendroctonus valens, is one of the most destructive forest pests in China, which is a secondary pest in its native range North America. It is urgent to understand its special behavior and underlying communications since the bark beetle mainly attack Chinese red pine Pinus tabuliformis, which is the main plantation in North China. Field investigation showed that RTB prefers to attack large pine trees and further analysis showed it is mediated by monoterpenes variation among variable size of pine trees. In field, RTB female adult initiates attack first, and one female and one male are in the same tunnel normally, which is the evident of monogamy. How this family structure is maintained? It shows that male who joined with female already, can prevent other male to meeting with its partner through the sound of stridulation to keep other males away. Besides, volatiles bioassay shows some pheromones have involved and GC-MS analysis shows that frontalin is released by feeding females, which functions as both sex and aggregation pheromone. Brevicomin is produced by male and acted as anti-aggregation pheromone, playing an important role in host shifting. Furthermore, male mating selection is evident that males always find large females to mate with, which could have more offspring. Underlying mechanisms are explored and shows that male could discriminate the size of tunnel and female itself through the amplitude (dB) of the drum-like sound produced by female. These are very useful to understand the invasion biology and to guide management.

Do novel fungal genotypes drive the success of an invasive bark beetle/pine host/fungus complex?

Min Lu[1], Jiang Hua Sun[2]

[1]Institute of Zoology, China, [2]Institute of Zoology, China

Novel genotypes often arise during biological invasions, but their role in invasion success has rarely been elucidated. Here we examined the population genetics and behavior of the fungus, Leptographium procerum, vectored by a highly invasive bark beetle, Dendroctonus valens, to determine whether genetic changes in the fungus contributed to the invasive success of the beetle/fungal complex in China. The fungus was introduced by the beetle from the US to China, where we identified several novel genotypes using microsatellite markers. These novel genotypes were more pathogenic to Chinese host seedlings than were other genotypes and they also induced the release of higher amounts of 3-carene, the primary host attractant for the beetle vector, from inoculated seedlings. This evidence suggests a possible mechanism, based on the evolution of a novel genotype during the two or three decades since its introduction, for the success of the beetle/fungal complex in its introduced region.

The role of kairomones in the mating sequence of cerambycid beetles

Jacob D. Wickham
Institute of Chemistry, Chinese Academy of Sciences, China

Regardless of whether or not species utilize pheromones, host kairomones play a critical role in the chemical ecology of the Cerambycidae, and are perhaps the most critically important, yet least understood steps in the sequence of reproductive behaviors of cerambycid beetles. Patterns are beginning to emerge regarding the various roles that host kairomones play in the lives of cerambycid beetles, and using recent empirical evidence, a synthesis of these ideas will be presented. Considerable research effort has been invested in developing pheromone-based lures for invasive or potentially invasive species, and there has been a recent surge in the number of species for which pheromones have been discovered, however, the exact roles of kairomones remains elusive. For some Monochamus and Tetropium spp., attraction to pheromones are synergized with host kairomones, while for other species, such as Anoplophora glabripennis, the exact role of host kairomones is not apparent. Previous reviews (Hanks 1999) have addressed how mate location strategies may be predicted by host condition. In this talk, the hypothesized mate finding 'strategies' of two pheromone-using cerambycids, one attacking stressed hosts, and the other attacking apparently healthy hosts, will be compared by discussing how host kairomones relate in the first step of the mating sequence in each 'strategy' (host selection), and then discuss how host kairomones are involved with female-produced and male-produced pheromones later in the sequence. Chemo-ecological risk assessment of European beech (*Fagus sylvatica*) stands along a precipitation gradient in Germany

Christine Rachow[1], Martin Gabriel[2], Stefan Schutz[3]
[1]University Gottingen, Germany, [2]University Gottingen, Germany, [3]University Gottingen, Germany

Volatile organic compounds (VOC), insect biodiversity and the olfactory perception of marker insect species were examined in European beech stands along a precipitation gradient in Northern Germany. Firstly, drought specific VOC as released by beech trunks and as detectable in beech stand air were measured throughout the years 2010/2011. In parallel, the species assemblies of phyllophagous insects, of xylophagous insects, and of antagonists were monitored. Secondly, beech specific insects were selected to examine their ability to detect drought specific VOC of beech. Olfactory detection of beech VOC was assessed utilizing gas-chromatography with parallel mass-spectrometric and electroantennographic detection (GC-MS/EAD). The identification of VOC specifically released by weakened beech trees and detected by insects attacking beech stands is an important step towards a chemo-ecologically based risk assessment of insect gradation. Utilizing biosensors on the basis of intact insect antennae can be a mean to develop a highly specific early warning system for forest stands under stress and prone to accelerated decline by secondary insect pests.

Direct and indirect effects of a Tospovirus on the behavior and biology of *Frankliniella fusca*, a Tospovirus vector

Rajagopalbabu Srinivasan[1], Anita Shrestha[2], David Riley[3], Albert Culbreath[4]
[1]University of Georgia, U.S.A., [2]University of Georgia, U.S.A., [3]University of Georgia, U.S.A., [4]University of Georgia, U.S.A.

Several circulative viruses are known to modify the behavior and biology of their vectors to benefit their own survival and spread. Tospoviruses are transmitted by thrips in a circulative and propagative manner. Very few studies conducted with a Tospovirus, Tomato spotted wilt virus (TSWV), and its vector, Frankliniella occidentalis (Pergande), have yielded mixed outcomes. Using peanut plants, we evaluated the effect of TSWV infection on settling and feeding behavior of Frankliniella fusca (Hinds). Also, effects on thrips oviposition and development were evaluated. TSWV infection in thrips and/ or peanut plants did not affect their settling pattern, but TSWV infection in thrips and peanut significantly impaired thrips feeding ability. TSWV infection in thrips increased their egg-laying capacity, but TSWV infection in peanut plants decreased their oviposition ability. In general, infections by circulative viruses are known to increase the concentrations of free amino acids in host plants, and amino acids have been known to influence oviposition in several insects. Evaluation of free amino acids in TSWV-infected and non-infected peanut plants indicated the presence of greater amounts of free amino acids, suggesting that amino acid increments could have led to increased thrips oviposition. TSWV infection in thrips significantly affected their survival and development. Despite the spike in free amino acid levels, TSWV-infection in peanut, overall, negatively affected the reproductive fitness of F. fusca. This suggested that free amino acids and possibly others might play a role in deceptive arrestment of thrips on TSWV-infected plants. Such an arrestment might be beneficial for TSWV spread.

How flowers attract pollinator beetles in annonaceous fruit trees?

Morio Tsukada[1], Keisuke Nagasawa[2], Toshiharu Akino[3]

[1]Mie University, Japan, [2]Mie University, Japan, [3]Kyoto Institute of Technology, Japan

The tropical fruit trees, cherimoya (Annona cherimola) and atemoya (A. cherimola x squamosa) are pollinated mainly by sap beetles (Coleoptera: Nitidulidae), which are attracted to floral odor. However, usually the natural fruit set is not enough so that hand pollination is required. To understand this rather primitive pollination system to replace costly hand pollination with beetle pollination, we explored chemical component of the floral odor of these trees. Odor was collected by in situ dynamic head space technique, and analyzed by GC and GC/MS. Most of the components were esters, with ethyl hexanoate, ethyl butanoate, ethyl octanoate, and ethyl hexanoate being main components. Protogynous hermaphrodite flower of these trees exhibit somewhat different composition of these esters between species and sexual stages (we could not obtain enough data for male stage flower of atemoya). As the result, principal component analysis clearly separated the two species and sexes. Because esters are main components of fruit odor in general, we hypothesized that theese flowers mimic fruits chemically to attract frugivorous sap beetles. We thus examined literature for data of fruit odor of cherimoya, atemoya and other fruit trees, as well as floral odor of other trees. We then employed principal component analysis for these data. The result showed that cherimoya and atemoya flowers are chemically very similar to their own fruits and fruits of other trees. We also examined quantitative change of the floral odor. The result will be discussed with diurnal rhythm of the pollinator beetles.

Odorant activation of insect olfactory receptors is inhibited by antagonism of the odorant receptor co-receptor subunit

Charles W. Luetje[1], Sisi Chen[2]
[1]*University of Miami , U.S.A.,* [2]*University of Miami , U.S.A.*

Insects detect attractive and aversive chemicals using several families of chemosensory receptors, including the OR family of insect odorant receptors, making these receptors appealing targets for the control of insects involved in disease propagation and agricultural damage. Insect ORs are odorant-gated ion channels, consisting of two essential parts: an odorant binding subunit and a co-receptor subunit (Orco). VUAA1 (CAS: 525582-84-7) was recently identified as a novel OR agonist that acts directly on Orco (Jones et al., 2011, PNAS 108: 8821-5). We screened ORs from several insect species using heterologous expression in Xenopus oocytes and electrophysiological recording, with a panel of compounds (termed Orco Ligand Candidates, OLCs) that were structurally related to VUAA1 (4-Ethyl-1,2,4-triazolothioacetamide core with alterations to the pyridine and phenyl rings) or similar to portions of the VUAA1 structure. OLC3 (pyridine nitrogen moved to the 4 position) and OLC12 (pyridine nitrogen in the 4 position and a 4-isopropyl moiety on the phenyl ring) were identified as agonists of the Orco subunit. We also identified a series of antagonists, each able to competitively inhibit OLC12 activation of Orco. A similar pattern of agonist and antagonist sensitivity was displayed by Orco subunits from different species, suggesting a highly conserved binding site structure. Importantly, we found that Orco antagonists could inhibit odorant activation of insect ORs through a non-competitive mechanism. Susceptibility to inhibition of odorant activation by Orco antagonism was conserved across disparate insect species, identifying Orco antagonism as a promising target for the development of novel, broadly active insect repellants.

Evolution of sex pheromone production and reception systems in Ostrinia moths

Yukio Ishikawa
The University of Tokyo, Japan

Mate-finding communication in many moths is mediated by the sex pheromones produced by females. Since differentiation of sex pheromones is often associated with speciation, it is intriguing to know how the changes in female sex pheromone have been tracked by the pheromone recognition system of the males. Moths of the genus Ostrinia, which show distinct differentiation in female sex pheromones, are good materials for studying the evolution of pheromone communication system. To detect the sex pheromones emitted by the conspecific females, males should have a system that can discriminate pheromone components and their ratios. In this system, odorant receptors (ORs) in the olfactory sensilla of male moths should play an important role in the specific recognition of pheromone molecules. We cloned seven OR genes (OscaOR1, OscaOR3?8) and an Orco homologue (OscaOR2), which is essential for the function of ORs, from the antennae of male Ostrinia moths. The results of functional assay of these ORs to pheromone components utilized in the genus Ostrinia will be reported. The response patterns will be discussed in terms of the evolution of sex pheromone production system in this genus.

Peripheral coding of sex pheromone blends with reverse ratios in two Helicoverpa species

Chen-Zhu Wang[1], Han Wu[2], Chao Hou[3], Xiao-Jing Jiang[4], Dan-Dan Zhang[5], Ling-Qiao Huang[6]

[1]Chinese Academy of Sciences, China, [2]Chinese Academy of Sciences, China, [3]Chinese Academy of Sciences, China, [4]Chinese Academy of Sciences, China, [5]Chinese Academy of Sciences, China, [6]Chinese Academy of Sciences, China

The two sibling sympatric species, Helicoverpa armigera and Helicoverpa assulta share two major sex pheromone components, cis-11-Hexadecenal and cis-9-Hexadecenal, but in reversed relative concentrations, 97:3 and 7:93, respectively. We combined behavior, electrophysiology, molecular biology and optical imaging to investigate the peripheral coding mechanisms in males to their sex pheromone blends with reverse ratios. Two groups of highly specific olfactory receptor neurons (ORNs) in two types of antennal sensilla are mainly involved in the pheromone coding, and each of them are tuned to one of the two components. As labeled lines, the two groups of ORNs each send unique information based on their firing rate, and continuously signal to the antennal lobe the levels of cis-11-Hexadecenal and cis-9-Hexadecenal in the air. The different sensitivity, abundance and distribution of the ORNs of each type further increase the differences between the two signals, detecting the ratio and reflecting importance of two components in the pheromone system of the two species. The parallel studies on the hybrids (F1) between H. armigera and H. assulta indicate that the number of ORNs of each type is an important factor affecting the accuracy of ratio detection. The olfactory receptors and associated transduction molecules contribute to the specificity and sensitivity of ORNs to the signals. The projection of the axons of ORNs to the male specific macroglomerular complex in the antennal lobe was also different between the two species. The central nervous system may compare the paired input and accordingly trigger the appropriate behavior.

Insects are heavily dependent on a well functioning olfactory system for more or less all activities. A plasticity in this system has also been shown to be advantageous. Here I will report on new data regarding the function of the insect olfactory co-receptor Orco. We have found that in the fruit fly Drosophila melanogaster Orco might work as a regulator of peripheral sensitivity . The data is unpublished but under review. I therefore provide no details. Please visit my talk.

Molecular genetic studies on the spli locus controlling pheromone preference in the silkmoth, *Bombyx mori*

Toru Shimada[1], Tsuguru Fujii[2], Huabing Wang[3], Takeshi Fujii[4], Hiroaki Abe[5], Akio Ohnuma[6], Yukio Ishikawa[7], Takashi Kiuchi[8], Susumu Katsuma[9]

[1]University of Tokyo, Japan, [2]University of Tokyo, Japan, [3]University of Tokyo, Japan, [4]University of Tokyo, Japan, [5]Tokyo University of Agriculture and Technology, Japan, [6]Institute of Sericulture, Dainippon Silk Foundation, Japan, [7]University of Tokyo, Japan, [8]University of Tokyo, Japan, [9]University of Tokyo, Japan

We have started the molecular genetic analysis of the 'polyphagous' mutants of B. mori, which feed not only mulberry but also the beet and other plant leaves. We succeeded in the positional cloning of two mutants, spli and Bt mapped on the Z chromosome, and found that both are alellic mutations of Bmacj6, a gene encoding a transcription factor with the POU-homeo domain. Recently, we found that the spli and Bt mutations do not affect not only food preference but also pheromone preference. Although the normal male adult is attracted by the female sex pheromone 'bombykol' ((10E,12Z)-hexadecadienol), the spli male is attracted by the aldehyde derivative, 'bombykal' ((10E,12Z)-hexadecadienal) (1). These results indicate that Bmacj6 controls both the food preference and pheromone preference through unknown transcriptional regulations. The mRNA expression of the bombykol receptor gene (BmOr1) was dramatically reduced in the adult male antennae of the mutants. We will introduce the recent progress in the comparative transcriptome analysis for finding the direct and indirect target genes of BmAcj6.

Coevolution of moth pheromone production and response in two model systems

Christer Jan Lofstedt[1], Dan-Dan Zhang[2], Jean-Marc Lassance[3]
[1]Lund University, Sweden, [2]Lund University, Sweden, [3]Lund University, Sweden

Communication depends on the mutual understanding of senders and responders. Sex pheromone communication in moths involves production of species-specific pheromones by females and their detection by conspecific males. Genes involved in pheromone production and reception have emerged via a birth-and-death evolutionary model. Enzymes and receptors with different specificities and sensitivities have evolved as a consequence of gene duplications and the resulting alteration of selective pressure and accumulation of mutations in daughter gene copies. We study two model systems from the perspective of pheromone evolution, the European corn borer Ostrinia nubilalis and the turnip moth Agrotis segetum. Pheromone production genes in O. nubilalis map to autosomes whereas three receptor genes with fixed allelic differences between pheromone races map to the male sex chromosome. Males and females produce similar pheromones by enzymes common to both sexes. The pleiotropic effects of genes could influence the trajectories of sexual signals and facilitate their divergence. Agrotis segetum produces a mixture of pheromone components including Z5-10:OAc, Z5-12:OAc, Z7-12:OAc and Z9-14:OAc. These and the behavioural antagonist Z5-10:OH and Z8-12:OAc elicit responses from specific receptor cells on the male antenna. Nine candidate pheromone-receptor (PR) genes belong to a subclade expansion previously described in Heliothis virescens PRs. Six of them cluster in the expansion of HR16 and show high amino acid sequence identity (71.0-97.7%). This suggests rapid evolution of PR genes in A. segetum. Functional characterization using Xenopus oocytes shows that substitutions at a few sites account for changes in ligand specificity and sensitivity.

Working Range of Stimulus Flux Transduction Determines Dendrite Size and Relative Number of Pheromone Component Receptor Neurons in Moths

Thomas Baker
Penn State University, U.S.A.

We are proposing that the relative abundances of the differently tuned pheromone-component-responsive olfactory receptor neurons (ORNs) on insect antennae are a result of specifically tuned sensillum-plus-ORN units having been selected to accurately transduce and report to the antennal lobe the maximal ranges of molecular flux imparted by each pheromone component in every plume strand. To not reach saturating stimulus flux levels from the most concentrated plume-strands of a pheromone blend, the dendritic surface area of the ORN type that is tuned to the most abundant component of a pheromone blend is increased in dendritic diameter in order to express a greater number of major-pheromone-component-specific odorant receptors (ORs). However, with the larger dendrite size and possibly other, high-flux-adjustments in titers of pheromone binding proteins and degrading enzymes comes a decrease in absolute sensitivity to lower flux levels of the major component in lower concentration strands of the pheromone blend. In order to restore the ability of the whole-antenna major-pheromone-component-specific channel to accurately report to its glomerulus the abundance of the major component in lower concentration strands, the number of major-component ORNs over the entire antenna is adjusted upward, creating a greater proportion of major-component-tuned ORNs than those tuned to minor components. Thus, we suggest that the two phenomena, dendrite size and relative numbers of differentially tuned ORNs are linked, and both are related to wide disparities in molecular flux ranges occurring for the more abundant and less abundant components in the pheromone blend plume-strands.

A novel control strategy against an invasive Argentine ant population by combining an insecticidal bait with a synthetic trail pheromone component

Sadahiro Tatsuki[1], Shun Suzuki[2], Eiriki Sunamura[3], Hironori Sakamoto[4], Koji Nishisue[5], Mamoru Terayama[6], Yukio Ishikawa[7], Hideaki Mori[8], Toshio Kishimoto[9], Yosaburo Utsumi[10], Takehiko Fukumoto [11]

[1]Univerisity of Tokyo, Japan, [2]Univerisity of Tokyo, Japan, [3]Univerisity of Tokyo, Japan, [4]Univerisity of Tokyo, Japan, [5]Univerisity of Tokyo, Japan, [6]Univerisity of Tokyo, Japan, [7]Univerisity of Tokyo, Japan, [8]Japan Wildlife Research Center, Japan, [9]Japan Wildlife Research Center, Japan, [10]Earth Biochemical Co., Ltd., Japan, [11]Shin-Etsu Chem. Co., Ltd., Japan

Control of the invasive Argentine ant, Linepithema humile in invaded areas is highly difficult. A major reason is undoubtedly formation of large-scale supercolonies (SCs). For effective control, treatment should be area-wide according to SC size, but it is virtually impossible to treat toxic agents throughout the habitat. Local treatment within a SC would cause rapid re-infestation in the treated area from surrounding untreated area. We then tried to incorporate synthetic trail pheromone (Z)-9-hexadecenal as a non-toxic as well as species-specific control agent into a control program. Based on the positive results obtained in preliminary small-scale field experiments with both insecticidal baits and a synthetic trail pheromone, we achieved a program to eradicate an Argentine ant population in Yokohama Port, one of major ports of entry, Japan. The population was first found at the port in 2007 and covered an area of about 6.7 ha. We initiated the program in April, 2008; insecticidal baits were deployed to suppress the population, and pheromone dispensers were treated to prevent expansion of its range. Within 18 months of the program, L. humile was eliminated from most of the study area using a relatively small amount of insecticidal bait. Expansion of its range did not occur during program, whereas native ants showed a marked recovery in abundance in the area once dominated by L. humile. The achievement at Yokohama Port may be a good example of controlling invasive ants at ports of entry, providing useful suggestions for effective and environmentally friendly control.

Control of *Riptortus pedestris*: Pheromone synthesis and trap development

Junheon Kim[1], Kwang-Sik Cho[2], Bu-Keun Chung[3], Chung Gyoo Park[4]

[1]Gyeongsang National University, Republic of Korea, [2]National Institute of Horticultural & Herbal Science, Republic of Korea, [3]Gyeongnam Agricultural Research & Extension Services, Republic of Korea, [4]Gyeongsang National University, Republic of Korea

Sweet (non-astringent) persimmon, Diospyros kaki Thunberg, is one of the important export fruits of Korea. For development of monitoring techniques and environmentally-friendly control strategies against the pests for exporting the fruit, integrated pest management is under investigation. Riptortus pedestris F. (= R. clavatus) (Hemiptera: Alydidae) is one of problematic pests of sweet persimmon in Korea and soybean in Asian countries. Monitoring and mass trapping of R. pedestris based on its aggregation pheromone has been applied by some famers. For enhancing pheromone-based control against R. pedestris, we developed new synthetic method for (E)-2-hexenyl (E)-2-hexenoate (E2HE2H) and (E)-2-hexenyl (Z)-3-hexenoate (E2HZ3), two components of the aggregation pheromone of R. pedestris, and also a new type of pheromone-baited trap. E2HE2H and E2HZ3H were synthesized by applying Steglich esterification method in various conditions. This synthetic method gave satisfied yield, shortened the synthetic process and lowered the cost. The newly designed pheromone trap, named symmetry trap, showed 6-28 times more trapping efficiency than a conventional trap. In this symposium, the results of synthesis for E2HE2H and E2HZ3H and the trap efficiency of newly developed trap will be discussed.

Success and fail in monitoring two sibling species of genus Matsumuraeses (Tortricidae) with same sex pheromone components in a same field

Jin Kyo Jung[1], Bo Yoon Seo[2], Jum Rae Cho[3], Chang-Gyu Park[4], Ki Hong Yum[5]

[1]RDA, Republic of Korea, [2]RND, Republic of Korea, [3]RDA, Republic of Korea, [4]RDA, Republic of Korea, [5]Greenagrotech, Republic of Korea

Matsumuraeses phaseoli and M. falcana are main insect pests to legumes. Laboratory colonies were established from larvae collected in red bean for M. phaseoli and in soybean for M. falcana, respectively in different regions. Sex pheromone studies were conducted to make monitoring tools for two species. The sex attractant of M. falcana was decided only through field experiments, while that of M. phaseoli was decided through analyses of pheromone gland extract and field experiments. It was concluded that the same three compounds, (E)-8-dodecenyl acetate, (E,E)-8,10-dodecadienyl acetate and (E,Z)-7,9-dodecadienyl acetate are used for the sex attractants of two species, but in different compositions, 1:7:2 for M. phaseoli, and 1:1:1 for M. falcana. The attractants were used for monitoring of annual occurrence of Matsumuraeses adults in a same field. The morphology of male genitalia was used for species-identification of adults caught in pheromone traps. Both species, however, were caught in the pheromone trap of each species. A clearly-different character between the two species was found in a nucleotide sequence of cytochrome oxidase I gene. The identification with the molecular character also showed the same results as the catch of both species in the pheromone trap of one species. Virgin female traps also gave the same results as the pheromone traps. The results indicated that the occurrence patterns of two species observed with pheromone trap should be corrected. Artificial hybridization experiments were conducted to confirm the sexual isolation between the two species. Finally, developmental characters were compared to analyze the monitoring results.

Sex pheromone blends for monitoring clearwing moths in Korean orchards

Chang Yeol Yang[1], Sung Jong Kim[2], Myoung Rae Cho[3]

[1]National Institute of Horticultural and Herbal Science, Republic of Korea, [2]National Institute of Horticultural and Herbal Science, Republic of Korea, [3]National Institute of Horticultural and Herbal Science, Republic of Korea

Clearwing moths (Lepidoptera: Sesiidae) are economically important pests of fruit trees, such as apple, pear, peach, and grape in Korea. Larvae feed on the cambial issue within tree branches of host plants, resulting in significant production losses. In this study, sex pheromone system and seasonal flight activity of four clearwing moths, Synanthedon haitangvora, Synanthedon bicingulata, Nokona regalis, and Glossosphecia romanovi, were studied. In field tests conducted at apple orchards, male S. haitangvora were optimally attracted to traps baited with a 5:5 mixture of Z3,Z13-18:OAc and E2,Z13-18:OAc. The maximum number of males S. bicingulata was attracted to a 4:6 blend of E3,Z13-18:OAc and Z3,Z13-18:OAc in peach orchards. While E3,Z13-18:OH as a single component was attractive to male N. regalis, high numbers of G. romanovi males were captured with a 9:1 ratio of Z3,Z13-18:OH and Z3,Z13-18:OAc in vineyards. The seasonal flight patterns of four clearwing moths were monitored with pheromone traps in Korean orchards. Male S. haitangvora were captured from May to October, with peak numbers in early June to middle June and late August to early September in apple orchards. S. bicingulata males were trapped from May to October, with peak catches in middle May to late May and early September in peach orchards. In vineyards, male N. regalis were captured from late May to middle June, but G. romanovi males were trapped from early June to late July.

Sex pheromone composition of *Ascotis selenaria* (Lepidoptera: Geometridae) and its regional variation in Korea

Kyungsan Choi[1], Young Mi Park[2], Kyung Hee Choi[3], Dong Hwan Kim[4], Dong Soon Kim[5]

[1]National Institute of Horticultural and Herbal Science, RDA, Republic of Korea, [2]National Plant Quarantine Service, Republic of Korea, [3]National Institute of Horticultural and Herbal Science, RDA, Republic of Korea, [4]National Institute of Horticultural and Herbal Science, RDA, Republic of Korea, [5]Jeju National University, Republic of Korea

This study was conducted to investigate sex pheromone composition of Ascotis selenaria (Lepidoptera: Geometridae) in Korea. Two sex pheromone compounds such as (Z,Z)-6,9-cis-3,4-epoxynonadecadiene (6Z,9Z-cis-3,4-epoxy-19:H) and (Z,Z,Z)-3,6,9-nonadecatriene (3Z,6Z,9Z-19:H) were identified in the glands of A. selenaria females by gas chromatography?mass spectrometry analysis. However, the component 3Z,6Z,9Z-19:H neither elicited an electroantennogram response nor increased the attractiveness for A. selenaria males in the field. The role of 3Z,6Z,9Z-19:Hseems to be as an antagonistic signal formating behavior of A. selenaria males. The blend ratios of two 6Z,9Z-cis-3,4-epoxy-19:H isomers such as, 6Z,9Z-cis-3R,4S-epoxy-19:H and 6Z,9Z-cis-3S,4R-epoxy-19:H, were critical to attract A. selenaria males. The blend ratios of the two isomers showing peak catch of A. selenaria males had large variations among the locations investigated. A. selenaria populations in Gunwi showed peak activity at ratios of 0.9:0.1 and 0.8:0.2, whereas the populations in Goheung, Yeongam, and Jeju (Aewol and Harye) showed peak activity at a 0.5:0.5 ratio. In Changnyeong, the peak activity occurred in a bimodal form at ratios of 0.7:0.3 and 0.4:0.6. Such variation was partially explained by geographical isolation due to mountain ranges. Consequently, the results of our study should be useful for designing a region-specific pheromone lure for successful A. selenaria monitoring.

Fire ant alarm pheromone and application

Man-Yeon Choi[1], Robert K. Vander Meer[2]
[1]USDA, U.S.A., [2]USDA, U.S.A.

The red imported fire ant, Solenopsis invicta, is among the world's 100 worst invasive alien species. In the United States this ant species infests more than 130 million hectares in southern tier states and Puerto Rico and are spreading northward. It is estimated to be responsible for almost $7 billion annually in damage repair, medical care, and control costs. The affected economic sectors are broad ranging and include households, electric service and communications, agriculture, schools and recreation areas. In the last decade S. invicta has changed from an invasive pest ant in the United States to a global problem, with infestations occurring in Australia, Taiwan, mainland China, Mexico and many Caribbean Island countries. Thus, novel control methods are needed and could result from manipulation of the fire ant alarm pheromone to disrupt mating flights or to in some way disrupt alarm pheromone production that could interrupt the normal insularity of fire ant colonies. We explored the changes of the amount of alarm pheromone amount in workers, female and male alates, and queens. We discovered that the pattern of alarm pheromone accumulation is different in the above distinct female castes and mating status. These results presented here could be lead to an understanding of how the alarm pheromone is used by fire ants in the various contexts of workers, female alates, and queens. This is the initial step in developing a novel fire ant control method from the interference of alarm pheromones in colony defense, mating flights, and colony development.

Effect of minor components on mating disruption of light brown apple moth

David Maxwell Suckling[1], Tes Sullivan[2], LD Stringer[3], RC Butler[4], DM Campbell[5], A Twidle[6], WJ Allen[7], A Mafra Neto[8], AM El-Sayed[9]

[1]The New Zealand Institute for Plant & Food Research Limited, New Zealand, [2]The New Zealand Institute for Plant & Food Research Limited, New Zealand, [3]The New Zealand Institute for Plant & Food Research Limited, New Zealand, [4]The New Zealand Institute for Plant & Food Research Limited, New Zealand, [5]The New Zealand Institute for Plant & Food Research Limited, New Zealand, [6]The New Zealand Institute for Plant & Food Research Limited, New Zealand, [7]The New Zealand Institute for Plant & Food Research Limited, New Zealand, [8]ISCA Technologies, Inc., U.S.A., [9]The New Zealand Institute for Plant & Food Research Limited, New Zealand

A new four-component sex pheromone blend for light brown apple moth (Epiphyas postvittana) was tested for efficacy of mating disruption in laboratory and field trials. Vineyard trials examined: a) the current two component ((E)-11-tetradecenyl acetate and (E,E)-9,11-tetradecadien-1-yl acetate, 95:5), b) a new four-component blend ((E)-11-tetradecenyl acetate and E,E-9,11-tetradecadien-1-yl acetate plus (E)-11-tetradecen-1-ol and (E)-11-hexadecenyl acetate (10:0.5:0.1:0.05)), c) higher ratio of the two new minor compounds (10:0.5:10:10), d) extra minors with an antagonist ((Z)-11-tetradecenyl acetate) added, e) extra minors with antagonist minus the most expensive component (E,E-9,11-tetradecadien-1-yl acetate), compared to f) untreated controls. In the laboratory, 69.0% of untreated pairs mated, and mating was suppressed by both attractive blends (41.1% mating (P=0.024, two component blend), and 18.4 % mating (P=0.003, four-component blend). In vineyards, totals of 24,776 and 41,053 male moths were caught in two trials, respectively, in delta traps baited with four-component lures and virgin females. Mating disruption was achieved at a higher level with a four-component blend for 13 / 14 weeks in trial 1 and for 10 / 10 weeks in trial 2. Disruption was improved by 12% with the four-component blend compared to the two-component blend (P=0.091). False trail following was unlikely to be as important as habituation or sensory overload, as the best formulation was only weakly attractive compared to virgin females.

Identification and assessment of a botanical termiticide from *Eremophila mitchellii*

Robert N Spooner-Hart[1], David N Leach[2], Karren Beattie[3], Albert H Basta[4], Amanda Reichelt-Brushett[5], Aaron Pollack[6]

[1]University of Western Sydney, Australia, [2]University of Western Sydney, Australia, [3]Southern Cross University, Australia, [4]University of Western Sydney, Australia, [5]Southern Cross University, Australia, [6]Southern Cross University, Australia

The wood of false sandalwood, Eremophila mitchellii, is resistant to termite attack in its natural environment; however, the properties conferring this resistance were unknown. Our research established that the essential oil from the heartwood of this species provides much of this resistance. Steam-distilled E. mitchellii wood oil exhibited toxic, repellent and antifeedant activity against the termites Nasutitermes exitiosus and Coptotermes acinaciformis in the laboratory. Detailed analysis of the oil was carried out by GC-FID, GC-MS, LCMS and NMR spectroscopy. After fractionation by preparative HPLC, eight components of the wood oil were characterized and accounted for >80% of the oil. Bioassay-guided fractionation determined that eremophilone and 8-hydroxy-1(10)- dihydroeremophilone were the principal active constituents in the oil. Pinus radiata wood impregnated with E. mitchellii oil was found to reduce damage by C. acinaciformis and Mastotermes darwiniensis in the laboratory, and by C. acinaciformis in the field.

Combined neem oil and eucalyptus oil lotion: In vitro and in vivo efficacy study for the treatment of head lice

Don Brushett[1], Prasutr Thawornchaisit[2], Weerawan Amornsak[3], Pakpimol Mahannop[4], Carol Morris[5]

[1]Southern Cross University, Australia, [2]Ministry of Health, Thailand, [3]Kasetsart University , Thailand, [4]Mahidol University, Thailand, [5]Southern Cross University, Australia

Biomimic Lice Lotion, an intermediate polarity formulation comprised of the natural products neem oil and eucalyptus oil, was tested for its pediculicidal and ovicidal efficacies in the treatment of head lice (Pediculus humanus var. capitis) infestations. Initial in vitro testing demonstrated pediculicidal and ovicidal efficacies of 95.7% and 100% respectively. A follow up clinical study of 45 female school children, with two lotion applications one week apart, showed significant in vivo activity. In the clinical study, pediculicidal efficacies of 92.9% and 96.6 % were measured two days after the first and second application of the lotion respectively. Similarly, the lotion also showed a high ovicidal efficacy of 80% and 100% respectively after each application. A questionnaire conducted at the conclusion of the trial indicated strong acceptance of the formulation by the participants and their parents.

Plant essential oils as repellents for agricultural pest management

Murray B. Isman[1], Claudio da Camara[2]

[1]*University of British Columbia, Canada,* [2]*Universidade Federal Rural de Pernambuco, Brazil*

Numerous plant essential oils and some of their major constituents have been shown to be insecticidal and/or repellent to several important insect pests. In particular, small soft-bodied insects (aphids, psyllids, thrips, whiteflies) and spider mites are susceptible and field trials in several countries suggest that pest management products based on plant essential oils can be efficacious as crop protectants. Under field conditions it is difficult to unambiguously demonstrate repellence as a mechanism of action, whereas laboratory studies have been unequivocal in that regard. Given the volatility of many essential oils and their constituents, formulations and slow-release devices may be necessary to ensure adequate residual action as repellents. We have recently found that certain essential oils from Citrus species can prevent or delay the movement of the two-spotted spider mite between plants in a greenhouse when applied to strings connecting plants. As strings are often used in greenhouse vegetable production to support growing plants, treated strings could limit the spread of spider-mite infestations in commercial greenhouses.

Bioactivity of extracts from *Tripterygium wilfordii* against insects

Xuping Shentu[1], Zheng Ma[2], Xiaoping Yu[3]

[1]China Jiliang University, China, [2]China Jiliang University, China, [3]China Jiliang University, China

Botanical pesticides provide an alternative to the use of synthetic pesticides with the advantages of greater public acceptance and reduction of environmental impacts. The Chinese medicinal plant, Tripterygium wilfordii Hook., has been shown to be a valuable source of biological pesticides. Our team investigated the bioactivity of alkaloids extracted from the root bark of T. wilfordii against larvae of striped stem borer (SSB), Chilo suppressalis, and diamondback moth, Plutella xylostella. In choice and no-choice tests, the median antifeeding concentration (AFC50) of the alkaloids against newly-hatched and 3rd instar SSB larvae were 188.3 mg L-1 and 22.5 mg L-1, 217.2 mg L-1 and 46.1 mg L-1 , respectively. The alkaloids also caused obvious growth inhibition in the SSB larvae, with growth-inhibition rates of 26.7% and 88.79% when alkaloid concentrations were 25 mg L -1 and 100 mg L-1 , respectively. The median lethal concentrations (LC50) for larvae treated for 24 h and 48 h were 676.4 mg L-1 and 326.5 mg L-1, respectively. The alkaloids also showed insecticidal activity against P. xylostella. The AFC50 of the alkaloids against 2nd instar P. xylostella larvae were 42.44 mg L-1 and 46.6 mg L-1 in choice and no-choice test, respectively . The LC50 for was 388. 5 mg L-1 for larvae treated for 72 h. The median effective growth inhibiting concentration (EC50)of alkaloids against 2nd instar larvae was 123.3 mg L-1. These studies provided a theoretical basis for further exploitation of T. wilfordii as a bio-pesticide.

Effect of guava fruit surface substances on oviposition behavior of oriental fruit fly (*Bactrocera dorsalis* Hendel)

Kai-ge Chen[1], Xinnian Zeng[2]
[1]*South China Agricultural University, China,* [2]*South China Agricultural University, China*

In order to investigate the role of host plant surface substances to oviposition behavior of oriental fruit fly (Bactrocera dorsalis Hendel), guava fruits removed surface substances and guava fruit surface substances extracts were tested to influence oviposition behavior of oriental fruit fly. The results showed that removing surface substance can significantly reduce oriental fruit fly choice rate to fruits and fecundity on guava fruit. Choice rate was lower than 50 % on each observation time, and the fecundity decreased rate was 26.34 %. Guava fruit surface substances extracts could attract oriental fruit fly and stimulate female adults to lay more eggs. The fecundity increasing rate of methanol extract to oriental fruit fly was 21.40 ± 0.70 %, this was more significantly than the fecundity increasing rate of dichloromethane extracts. The stimulatory activity of methanol extracts to oriental fruit fly was dose dependent. The oviposition percentage was from 8.44 % to 32.00 % when the methanol extracts concentration was used from 0 to 10 gfe/mL. We also found that oriental fruit fly could lay eggs only existing guava fruit flesh volatiles.

Development and use of a natural plant extract (semiochemical) for the management of pests and beneficial insects on cotton cropping systems in Australia

Robert Kofi Mensah[1], Nick Watts[2], Alison Young[3]
[1]NSW Department of Primary Industries, Australia, [2]Growth Agriculture Pty Ltd, Australia, [3]SACOA Pty Ltd, Australia

Cotton crops worldwide continue to face pest problems whether it is conventional or genetically engineered crops. While adoption of transgenic crops has resulted in the reduction of synthetic insecticide use against lepidopteran pests (eg Helicoverpa spp.), there have been rapid increase in populations of sucking pests because they are unaffected by the Bt toxin expressed in the transgenic crops. These pests continue to cause significant damage to both transgenic and conventional cotton crops. One of the approaches is the use of natural plant chemical compounds or plant extracts. Studies were undertaken between 2001-2010 to develop a semiochemical for integrated pest management (IPM) on cotton crops. An Australian Native plant code-named Plant X was identified as having behaviour modifying compounds that can potentially deter insect egg lay, feeding as well as cause direct mortality to pests. The Plant X bioactive compounds were formulated and assessed against pests in a series of field trials on cotton crops. The study showed that application of 2 L/ha or 2% v/v of the Plant X product reduced Helicoverpa spp. egg lay and controlled 1-3rd instar larvae. Also, the product reduced populations of adults and nymphs of Bemisia tabaci, Creontiades dilutus and Aphis gossypii. The product was also found to have no significant effect on predatory beetles, bugs, lacewings and spiders when applied at 1.0, 1.5 and 2.0 L/ha rates. Therefore, the use of Plant X (semiochemical) product will enhance conservational biological control, support IPM and reduce overall pesticide use against pests on cotton crops.

Electrical penetration graphs during brief phloem punctures by aphid stylets

Freddy Tjallingii
EPG systems, Netherlands

Aphids often insert their stylets into sieve elements without subsequent typical phloem phase activities, phloem salivation and phloem ingestion, as reflected by EPG waveforms E1 and E2, respectively. Mostly the potential drop (pd) waveforms from a sieve element cannot be distinguished from pds in other cells, except for a few species, which show repetitive potential drops (r-pds). These regularly repeated r-pds are longer and show somewhat different waveform features, on which will be reported in this presentation. In addition to the waveform differences, the SE cells differ in an important aspect from non-SE cells, i.e. SE cells have no vacuoles. The normal pd may have a period during which the stylet tips are inside the vacuole. A vacuole tip position during pd sub-phase II-2, could explain that sub/phase has not be correlated to non-persistent transmission of plant viruses. This aspect will be focused as well.

Role of immune regulators in controlling aphid / plant interactions

Geraldine Dubreuil[1], Philippe Giordanengo[2], Didier Crochard[3], Emeline Deleury[4], Antonin Schmitz[5], Jean-Christophe Simon[6], Christine Coustau[7]

[1]Institut Sophia Agrobiotech, France, [2]Institut Sophia Agrobiotech, France, [3]Institut Sophia Agrobiotech, France, [4]Institut Sophia Agrobiotech, France, [5]Institut Sophia Agrobiotech, France, [6]INRA Rennes, France, [7]Institut Sophia Agrobiotech, France

A striking observation coming from the analysis of the pea aphid genome was the absence of some genes known to be involved in the immune responses of other insects. In contrast to this apparent limitation in the antimicrobial arsenal, we identified 6 genes coding for the cytokines MIFs within the A. pisum genome. In mammals, MIFs are key regulators of the innate immune response. To start investigating the role of ApMIFs in the aphid biology, we analyzed their expression and showed a negative correlation between ApMIFs expression levels and the presence, or the establishment of secondary symbionts. By contrast, ApMIFs expression levels increased upon infection with a parasitoid or a non-mutualistic bacterium, demonstrating that expression levels differentially vary during agonistic or antagonistic interactions. Surprisingly, one ApMIF was found expressed in the salivary glands raising the question of the role of this immune regulator in the aphid-plant interaction. We therefore investigated the effect of ApMIF expression knock-down on aphid feeding behavior. Interestingly, a 60% reduction in expression of members from the multigenic ApMIF family correlated with a significant disruption of the feeding behavior, as analysed by the electrical penetration graph technique (EPG). These results showed that the ApMIF multigene familly may be involved in the interaction with symbionts and that it plays a key role in controlling the ability of the aphid to properly exploit and feed on their host plant.

Behaviour and physiology of aphids related to potato resistance

Yvan Pelletier[1], Julien Pompon[2]

[1]Potato Research Centre, Canada, [2]University of New Brunswick, Canada

Crop resistance to insect is seen as the best approach to reduce the use of insecticide in crop protection. Wild Solanum species are used as a source of resistance to aphids for the development of new cultivars. The study of aphids host selection behaviour on resistant germplasm provides insight on the mode of resistance present in the wild Solanum parent. This approach also led to redefine the role of xylem sap consumption in aphids as a strategy to regulate the osmotic pressure of the haemolymph.

Unravelling the mechanisms of resistance to bluegreen aphid and pea aphid in the model legume *Medicago truncatula*

Karam Singh[1], Lars Kamphuis[2], Sumin Guo[3], John Klingler[4], Lingling Gao[5], Owain Rhys Edwards[6]

[1]University of Western Australia, Australia, [2]CSIRO, Australia, [3]Nanjing Forestry University, China, [4]CSIRO, Australia, [5]CSIRO, Australia, [6]CSIRO, Australia

Aphids, including the closely related bluegreen (BGA; Acyrthosiphon kondoi) and pea (PA; A. pisum) aphid, are important pests in agriculture. Resistance to BGA and PA has been introgressed into the Medicago truncatula variety Jemalong (A17) through recurrent backcrosses to create a new aphid-resistant cultivar Jester (91% identical to A17). Resistance to BGA in Jester is conferred by a dominant gene called AKR (Acyrthosiphon kondoi resistance) located on the short arm of chromosome three in a region rich in CC-NBS-LRR genes. PA resistance in Jester is conferred by a dominant gene, termed APR (Acyrthosiphon pisum resistance), which lies approximately 22.3 cM distal from AKR in a region dense in CC-NBS-LRR genes. Analysis of transcriptional changes in defence related genes representing various signalling pathways and transcription factor profiling showed clear differences in the response to BGA vs. PA. A17 has a moderate resistance to both BGA and PA compared to the highly susceptible accession A20. Quantitative trait loci (QTL) analysis using an A17 x A20 recombinant inbred line population revealed that one locus, which co-segregated with AIN (Acyrthosiphon induced necrosis) on chromosome 3, is responsible for the reduction of aphid biomass (indicator of antibiosis) for both PA and BGA, albeit to a lesser degree for PA than BGA. Interestingly, two independent loci on chromosomes 5 and 3 were identified for the plant biomass reduction (indicator of plant tolerance) by PA and BGA, respectively, demonstrating that the plants tolerance response to these two closely related aphid species is distinct.

Plant vigour and amino acid content and host utilisation by free-living eucalypt psyllids

Martin Steinbauer
La Trobe University, Australia

Psyllids exhibit either lerp-forming or free-living nymphal biologies. The nymphs of lerp-forming species are restricted in the tissues they can access to those immediately below their lerps. Consequently, the amino acid requirements of different species can either be met by females laying on expanding tissue (young leaves) or by nymphs altering already expanded leaves through the salivary enzymes they secrete into plant tissues (e.g. when on old leaves). Free-living psyllids appear to have circumvented such restrictions by laying into rapidly growing shoots which are presumably supplied with photosynthate already high in amino acids. Free-living psyllids may therefore provide models for lerp-forming species that prefer to oviposit on young foliage. The assumption that free-living psyllids exhibit a preference for high vigour plant parts because they are higher quality resources has not been examined (at least not for Australian taxa). I will present the findings of a study that compared two species of Ctenarytaina host specific for two species of eucalypt that differ in plant vigour and consider how they answer this assumption.

Use of Fluorescence, a novel technique to determine reduction in feeding of phloemophagous insects when exposed to CyazypyrTM and other insecticides

Juan Manuel Alvarez[1], Rachel A Cameron[2], Edward B Lang[3], Hector E. Portillo[4], Jason D Scott[5], I Billy Annan[6]
[1]DuPont, U.S.A., [2]DuPont, U.S.A., [3]DuPont, U.S.A., [4]DuPont, U.S.A., [5]DuPont, U.S.A., [6]DuPont, U.S.A.

Phloemophagous insects are extremely economically important pest in the multiple crops in the World. Growers in many places rely on the use of insecticides to reduce populations of these insects. However, insecticides may take a few days to cause insect mortality and some do not reduce feeding. Reducing feeding of whiteflies and aphid would decrease the physiological effects on plants as well as the sooty mold and potentially the transmission of viruses. Measuring the reduction in feeding after the exposure of Bemisia.tabaci and Myzus persicae to an insecticide has proven difficult. A novel technique was developed to assess the effect of insecticides in the feeding of these phloemophagous insect species. A series of laboratory experiments demonstrate the usefulness of fluorescence in determining B. tabaci and M. persicae feeding cessation. Fluorescein sodium salt is systemically absorbed by plants and also by the insects feeding on these plants. Insects start fluorescing shortly after the plant root system is submerged in the fluorescein sodium salt. The effect of three insecticides (CyazypyrTM, imidacloprid and spirotetramat) with different modes of action on the reduction in feeding of these phloemophagous insects was evaluated and compared using this novel technique. It was determined that B. tabaci nymphs and M. persicae feeding on a plant treated with CyazypyrTM have a significant reduction of feeding when compared to nymphs feeding on plants treated with imidacloprid and spirotetramat.

Resistance of sugarcane, *Saccharum* spp., to the sugarcane aphid, *Melanaphis sacchari* (Zehntner) (Hemiptera: Aphididae), the vector of *Sugarcane yellow leaf virus*

Benjamin Fartek[1], Samuel Nibouche[2], Patrick Turpin[3], Laurent Costet[4], Bernard Reynaud[5]

[1]CIRAD, Universite de la Reunion, France, [2]CIRAD, France, [3]CIRAD, France, [4]CIRAD, France, [5]CIRAD, France

The sugarcane aphid Melanaphis sacchari (Zehntner) (Hemiptera: Aphididae) is the main vector of the *Sugarcane yellow leaf virus* (SCYLV; genus Polerovirus, family Luteoviridae), a disease of economical importance in the sugarcane growing area. Resistance was detected in the sugarcane cultivar R 365, using a three-year field trial in La Reunion island. In laboratory, R 365 reduced aphid populations on potted plantlets and excised leaves. Using the electrical penetration graph technique, we detected a delayeddelayed aphid salivation in phloem and inhibition of passive phloem sap uptake in R 365. Future research to evaluate the resistance durability and efficiency against Melanaphis sacchari diversity and its potential for reduction of SCYLV incidence through sugarcane cultivation schemes will be discussed

Cross talks between plant and insects can be perceived by infecting viruses: Putative ecological consequences

Stephane Blanc[1], Aurelie Bak[2], Alexandre Martiniere[3], Martin Drucker[4]
[1]INRA, France, [2]INRA, France, [3]INRA, France, [4]INRA, France

Most plant viruses are transmitted by vectors, particularly by hemipteran insects. The interactions between plants, viruses and insect vectors are obviously highly sophisticated, but they remain only very fragmentarily understood. Indeed, while countless reports have focused on two way interactions between the couples plant-insect, plant-virus, and virus-insect, the studies actually addressing three ways interactions in this type of biological system remains extremely scarce. The impact of plant viral-infection on the insect behavior have sometimes been addressed, reporting for example increased insect attraction due to changes in leaf colors, in volatile emission, or in sap composition. Surprisingly enough, despite the fact that common defense pathways are induced in plants by viral infection and by insect attack, a possible impact of the insect colonization of the plants onto the viral infection cycle has never been addressed. We have recently demonstrated that Cauliflower mosaic virus (CaMV) is able to highjack the plant perception of aphid feeding, and to immediately react by producing transmission specific morphs within infected plant cells. Interestingly, we demonstrated that non-aphid stresses such as wounding, or exposure to CO2-saturated atmosphere is provoking the same CaMV reaction, correlatively enhancing the efficiency of vector-transmission. This discovery is opening a wide new horizon for research in this field, evaluating the possible range of viral reactions to the feeding of insect vectors, and the range of unrelated biotic or non-biotic stresses that can "falsely" provoke these viral reactions and increase transmission.

Characterising interactions between the common brown leafhopper *Orosius orientalis* and selected nutritional sources

Piotr Trebicki[1], W Fred Tjallingi[2], Rob M Harding[3], Brendan Rodoni[4], Kevin Steven Powell[5]

[1]DPI-Victoria, Australia, [2]Laboratory of Entomology, Netherlands, [3]Centre for Tropical Crops and Biocommodities, Queensland University of Technology, Queensland, Australia, [4]DPI-Victoria, Australia, [5]DPI-Victoria, Australia

Orosius orientalis (Hemiptera: Cicadellidae), he common brown leafhopper, is a polyphagous vector of a range of economically important pathogens, including phytoplasmas and viruses, which infect a diverse range of crops. This polyphagous pest affects a range of economically important crops yet fundamentals of its feeding behaviour have been largely unexplored. Studies on the plant penetration behaviour by O. orientalis were conducted using the electrical penetration graph (DC-EPG) technique to assist in the characterisation of pathogen acquisition and transmission. EPG waveforms representing different probing activities were acquired from adult O. orientalis probing in planta, using two host species, tobacco Nicotiana tabacum and bean, Phaseolus vulgaris, and in vitro using a simple sucrose-based artificial diet. Five waveforms (O1-O5) were evident when O. orientalis fed on bean, whereas only four waveforms (O1-O4) and three waveforms (O1-O3) were observed when the leafhopper fed on tobacco and on the artificial diet, respectively. Both the mean duration of each waveform and waveform type differed markedly depending on the food substrate. Waveform O4 was not observed on the artificial diet and occurred relatively rarely on tobacco plants when compared with bean plants. Waveform O5 was only observed with leafhoppers probing on beans. The attributes of the waveforms and comparative analyses with previously published Hemipteran data is presented and discussed, but further characterisation studies will be needed to confirm our suggestions.

Impact of leafhoppers that vector phytoplasma in oilseed crops in the Canadian prairies

Chrystel Olivier[1], Brian Galka[2]

[1]*Agriculture and Agri-Food Canada, Canada,* [2]*Agriculture and Agri-Food Canada, Canada*

The main oilseed crop grown in Western Canada is canola (mostly Brassica napus). False flax (Camelina sativa) is considered to be an alternative oilseed platform for the prairies due to its resistance to drought and to most diseases and insect pests. Aster yellow (AY) is caused by the phytoplasma species 'Candidatus Phytoplasma asteris', which is transmitted mainly by leafhoppers. In canola and false flax, AY is generally considered of little significance, with overall incidence less than 1%. However, over the past decade, several epidemics occurred with incidence reaching 40% in some fields. Plants and leafhoppers were sampled in camelina and canola fields throughout Saskatchewan (Canada) between 2001 and 2011. Disease incidence and yield losses were determined and phytoplasma infecting plants and insects were identified using PCR tests and DNA sequencing. No variation in disease incidence was observed between canola cultivars. However, camelina germplasms exhibiting no AY symptom were detected. The presence of phytoplasma DNA in canola and camelina seeds and seedlings will be discussed.

Insect vectors of plant pathogens threatening agricultural production in Sudan

Abdalla Abdelrahim Satti
Environment and Natural Resources Research Institute, Sudan

Several biotic and abiotic factors contribute to spreading of plant diseases and their transmissions among different host plants are well documented. However, insects are important biotic agents causing widespread distributions and outbreaks of many pathogenic infections in the field. For instance, the repeated epidemic outbreaks of the leaf curl viral disease in cotton and tomato crops are merely correlated to the high activities of Bemisia tabaci populations in different countries. Accordingly, this paper sheds light on the important species of insects involved in transmitting deleterious plant pathogens of economic significance in Sudan. About fifteen insect species (pests and non pests) reported as vectors of more than twenty plant pathogens, mostly viruses, were listed. Some insect pests, such as B. tabaci, Aphis craccivora and Aphis gossypii, were known to transmit complex of over five different destructive plant viruses, including leaf curl, mosaic, stunting, wilting, mottling, rosette and vein thickening viruses. Moreover, the magnitudes of damage inflicted on some major host plants were also outlined. Hence, some control measures proved to be successful against certain vectors in the country were suggested to be integrated for their management.

Investigating the impact of elevated CO2 on wheat, Barley yellow dwarf virus and its aphid vector *Rhopalosiphum padi*

Piotr Trebicki[1], Angela Freeman[2], Rebecca Vandegeer[3], Kevin Steven Powell[4], Glenn Fitzgerald[5], Nilsa A. Bosque-Perez[6], Jo Luck[7]

[1]Department of Primary Industries (DPI) Biosciences Division Private Bag 260, Australia, [2]Department of Primary Industries (DPI) Biosciences Division Private Bag 260, Australia, [3]Department of Primary Industries (DPI) Biosciences Division Private Bag 260, [4]DPI-Victoria, Australia, [5]DPI, Private Bag 260, Australia, [6]University of Idaho, U.S.A., [7]DPI, Private Mail Bag 15, Ferntree Gully Delivery Centre, Australia

Climate change is a concern globally due to a possible impact on the environment and especially on agriculture. Predicted changes in CO2 and temperatures may have a major impact on agricultural systems. Nevertheless, there is a lack of empirical data on the effects of elevated CO2 and temperature on agricultural pest and pathogen populations. Consequently, predictions on the future of our major monoculture crops such as wheat, have not been fully understood. In a joint effort, the Department of Primary Industries Victoria, the University of Melbourne and the Department of Climate Change have established a Free-Air CO2 Enrichment (FACE) facility at Horsham, Victoria to study the effects of elevated CO2 on wheat production in Australia. The FACE facility in Horsham is being used to study the effects of projected CO2 concentrations (550ppm) under field conditions on wheat, the Barely yellow dwarf virus (BYDV) as well as the population dynamics and biology of its aphid vector Rhopalosiphum padi (Homoptera, Aphididae). Results from our studies on wheat plants under FACE conditions showed positive response to elevated CO2. However, variable field conditions have proved problematic for studying the impact of elevated CO2 on BYDV and its vector, thus in addition, controlled environment growth chambers were used to study in detail, the physiology and feeding behaviour of R. padi and its ability to acquire and transmit BYDV under different CO2 concentrations. Results from both the FACE and growth chamber experiments will be presented and the potential ecological and epidemiological consequences discussed.

Vegetable oil for PVY control

Arnaud Ameline[1], Mounia Khelifa[2], Solene Garson[3], Christine Rusterucci[4], Josselin Penisson[5], Philippe Giordanengo[6]

[1]Universite Picardie Jules Verne, France, [2]Universite Picardie Jules Verne, France, [3]Universite Picardie Jules Verne, France, [4]Universite Picardie Jules Verne, France, [5]Universite Picardie Jules Verne, France, [6]INRA, France

Potato virus Y (PVY) is a phytopathogen virus transmitted in a non-persistent manner by aphids to a broad range of crops. Mineral oil application has been considered for several decades as an effective mean to protect plant against virus damages. Recently we demonstrate that mineral oil has no negative effect on insect fitness or its feeding behaviour but affect mainly the vector virus acquisition step. Furthermore we show that the treatment of potato plant by rapeseed oil prior to viruliferous aphid infestation, can also lead to a reduction in PVY transmission. In order to propose an alternative to mineral oil treatment, we investigated the effect of rapeseed oil treatment on potato plants on the feeding behaviour and fitness of Myzus persicae (Hemiptera, Aphididae). The electropenetrography technic is used to point out feeding item link to acquisition. We demonstrate divergent effects of plant treatment (oil-treated or not) and virus infection (PVY infected or not) on aphid feeding behaviour, growth and reproduction. This work brings new insights into our understanding of mineral and vegetable oils mode of action and more generally of the mechanisms governing the PVY epidemiological dynamics.

Insect related Interactions at a Multi-trophic Ecosystem

Aphids acquired symbiotic genes from bacteria

Atsushi Nakabachi
Toyohashi University of Technology, Japan

Aphids harbor an obligate mutualist, Buchnera aphidicola (Gammaproteobacteria), within the cytoplasm of specialized cells called bacteriocytes. Since the initial infection in a common ancestor of aphids more than 100 million years ago, Buchnera have been subjected to strict vertical transmission through host generations, and the mutualism between Buchnera and their host has evolved to the point that neither can reproduce in the absence of the other. During the course of coevolution with the host, Buchnera has lost a number of genes that are considered essential for bacterial existence. The genome of Buchnera from the pea aphid, Acyrthosiphon pisum, encodes about 620 genes (genome size: 650 kb), which is only one seventh of that of most related free-living bacteria, such as Escherichia coli. Our studies including genomic and transcriptomic analyses revealed that the pea aphid acquired 12 genes/gene fragments from bacteria via lateral gene transfer. Buchnera was the apparent source of two highly truncated pseudogenes. Most other transferred genes were closely related to genes from relatives of Wolbachia (Alphaproteobacteria), which are absent in the analyzed aphids. At least eight of the transferred genes appear to be functional, and seven are highly transcribed in bacteriocytes. The results excluded the hypothesis that genome reduction in Buchnera has been accompanied by gene transfer to the host nuclear genome, but strongly suggest that aphids utilize a set of genes transferred from other bacteria in the context of the Buchnera?aphid mutualism.

Predicting the effects of climate change on mealybugs and their natural enemies in grapevines in Australia

Linda Thomson[1], Ary Hoffmann[2]

[1]*University of Melbourne, Australia,* [2]*University of Melbourne, Australia*

Pest damage will depend on individual pest effects, changes in pest complexes and relevant natural enemies. We looked at potential for change in the relative importance of mealybug species in Australian vineyards. Distributions of two commonl native species longtailed mealybug Pseudococcus longispinus (Targioni Tozzetti), and citrophilus mealybug Pseudococcus calceolariae (Maskell) were mapped from pest records and potential responses under climate change modelled using MAXENT. Lethal temperatures were determined in our laboratory by subjecting individuals to temperature treatments for 2 h and compared to available data for a potentially invasive, vine mealybug Planococcus ficus (Signoret) taken from published limits. Vine mealybug, while currently not present in Australia, has shown itself to be an efficient invader, now a key pest in Europe, Africa, South Africa, Argentina, the Middle East, California and Mexico, and currently regarded as a potential threat to the Australian industry. Vine mealybug has a number of traits that may make it particularly damaging and difficult to control, including a potential for faster population growth resulting from more generations per year and ecological changes. It may also be a more efficient transmitter of grapevine leafroll viruses, a cause of increasing concern in grape growing regions globally. Of the many natural enemies of mealybugs, we looked at thermal responses of a predator, ladybird beetle Cryptoleamus montrouzieri Mulsant and a parasitoid Leptomastix dactylopii Howard. Responses of the pest and natural enemies were compared to investigate potential changes in the control efficacy of the natural enemies through changes in their distribution and abundance.

Keywords:*vine mealybug, longtailed mealybug, ladybird beetle, citrophilus mealybug, parasitoid*

Trophic interactions along climatic gradients with *Neodiprion sertifer* as a model species

Ida Kollberg[1], Helena Bylund[2], Christer Bjorkman[3]

[1]Swedish University of Agricultural Sciences, Sweden, [2]Swedish University of Agricultural Sciences, Sweden, [3]Swedish University of Agricultural Sciences, Sweden

A frequently recurring question is if problems with insect pests in forests and agricultural crops will become more intense in a future, warmer climate. Higher temperatures are favorable for insects by increasing their activity and shortening the development time, thereby reducing the time exposed to natural enemies. On the other hand, higher temperatures will also affect the natural enemies and the host plant of the insect, and as a consequence change the relative importance of the mechanisms regulating the population. By studying temperature effects on interactions driving population dynamics we hope to become able to predict the future performance and outbreak risk of pest insects. We have studied the effect of temperature on the performance (survival, development time and weight) of a forest defoliating insect, the European pine sawfly, Neodiprion sertifer (Hymenoptera: Diprionidae) in the laboratory and in a latitudinal gradient in the field. Preliminary results suggest different responses to temperature from insect larval predators and mammalian pupal predators in this system, indicating that predation rate on larvae may increase while the pupal predation rates could decrease. The direct effects on the sawfly were as expected: higher temperatures reduced development time mainly in the younger larval stages and resulted in a lower final cocoon weight. Our results imply that the relative importance of different regulatory mechanisms for a species (e.g. food quality and predation by different types of natural enemies) may change with increasing temperatures and thereby affect the probabilities for outbreaks.

Climate change impact on extrinsic and intrinsic competition between egg parasitoids

Antonino Cusumano[1], Ezio Peri[2], Stefano Colazza[3]

[1]University of Palermo, Italy, [2]University of Palermo, Italy, [3]University of Palermo, Italy

Climate changing is a real phenomenon and the last decade was the warmest decade ever. The impact of climate change on animal communities is complex, affecting species interactions in all trophic levels, in different ways and in different bio-geographic zones. Here we will discuss about the possible effects of climate changes in shaping the competition between egg parasitoid species to consume the same hosts. Egg parasitoids are important biological control agents due to their ability to kill the pest before the crop-feeding stages emerge. Competitive effects can be divided in "extrinsic competition", the indirect interactions between adult females searching for hosts, and "intrinsic competition", the competition that occurs between larvae developing in the same host. The climate change impact will be addressed taking into account: 1) how quantitative and qualitative variation in plant volatile organic compound (VOC) emission may affect extrinsic competition; 2) how changes in host's biology may affect intrinsic competition as consequence of global warming. Finally data on intraguild interactions under global warming scenario between two sympatric egg parasitoids of a true bug will be presented.

Efficiency of volatile multitrophic signals under changing environmental conditions

James Blande
University of Eastern Finland, Finland

Plants produce and emit a complex array of volatile organic compounds (VOCs). The blend of these chemicals is substantially altered depending on the physiological state of the plant. Feeding by herbivores, infection by pathogens and numerous abiotic stressors elicit quantitative and qualitative changes in the volatile chemical blend. Numerous interactions between plants and their community members are mediated by these chemicals and are often specific to the stress induced chemical blend. These interactions include the attraction or repulsion of herbivores, the attraction of predators and parasitoids and plant-plant communication. One of the biggest challenges to the field of chemical ecology is the interpolation of laboratory collected behavioural data to the larger ecological scale. At this juncture, plants are exposed to combinations of abiotic factors, which may stress plants or act directly on the volatile chemical messengers that they emit. Ground-level ozone, concentrations of which have risen over the course of the last century, is one such factor. Ground-level ozone exerts oxidative stress on plants and induces the emission of VOCs. In addition, it breaks down numerous VOCs, altering the composition of the chemical blend and reducing the distance over which it remains intact. In this talk I will discuss the implications of changing environmental conditions on the volatile-mediated interactions occurring in multitrophic systems.

Invaders, parasitoids and cyclic resident dynamics - A fatal equation?

Tea Ammunet[1], Tero Klemola[2], Kalle Parvinen[3]

[1]*Swedish University of Agricultural Scieces, Sweden,* [2]*University of Turku, Finland,* [3]*University of Turku, Finland*

The mountain birches in boreal Fennoscandia have, for centuries, been periodically defoliated by a resident geometrid moth, Epirrita autumnata. The densities at the peak phases of the cyclic population fluctuations may lead to death of vast birch forest areas. Recent empirical studies have confirmed the importance of parasitoids in driving these population cycles. The global warming, has, however, brought a new factor to the complex moth-parasitoid dynamics as another cyclic geometrid, Operophtera brumata, has expanded its outbreak range to Finnish Lapland. This closely related invader has spread due to warming winters and has already caused severe defoliation and tree deaths on the host it shares with the resident E. autumnata. In addition, the two moths have common parasitoids in these areas. Asymmetric preferences of both parasitoids and predators have been observed between the moth species in earlier studies. As invasive species can have profound effects on resident community via indirect trophic interactions, it is important to study the consequences of asymmetries on population level. Observing the effects may, however, be difficult when studying cyclic populations. A modelling approach was therefore used to see the potential consequences of the recent invasion on resident population dynamics. Utilising empirical data from northern Fennoscandia, we modelled the invasion to the ecosystem. The coexistence of the two moth species and effects of indirect interactions on the long term population dynamics were then analysed. Independent of the modelled dynamics, the invasive species was observed have the potential to inflict drastic changes in the mountain birch community.

Constant versus fluctuating temperatures in the interactions between *Plutella xylostella* and its larval parasitoid *Diadegma insulare*

Md Habibullah Bahar[1], Juliana Soroka[2], Lloyd Dosdall[3], Owen Olfert[4]

[1]Agriculture Agri-Food Canada, Canada, [2]Agriculture Agri-Food Canada, Saskatoon Research Centre, Canada, [3]University of Alberta, Canada, [4]Agriculture Agri-Food Canada, Canada

Using three constant (7, 22 and 30°C) and three corresponding fluctuating temperatures (0-14, 15-29 and 23-37°C), laboratory studies were conducted to determine the effects of different temperature regimes on the interactions between the insect pest, diamondback moth (DBM), Plutella xylostella (Lepidoptera: Plutellidae) and its parasitoid Diadegma insulare (Hymenoptera: Ichneumonidae). Parasitized third instar DBM larvae were reared until adult mortality in different temperature regimes in individual thermal gradient cells. Different biological parameters, including larval mortality, successful parasitisation rate, pupal mortality, larval and pupal development time, adult longevity, pupal weight, pupal shell weight, and adult dry weight were recorded. The highest parasitism rate (70%) was found at temperature regimes of constant and fluctuating 22°C and fluctuating 7°C, and the lowest parasitism was (30%) at fluctuating 30°C. At all temperature regimes, the mortality of D. insulare pupae was higher than that of DBM pupae; these differences were larger at higher temperatures. There were longer development times and higher pupal body masses at lower temperatures for both insects. Fluctuating compared to constant temperatures caused shorter development times, similar body mass and higher adult longevity for both insects in optimal and lower temperature ranges; however, fluctuation around the highest temperature did not cause such consistent patterns. Therefore, fluctuating temperatures as found in nature must be taken into account when conducting thermal studies in the laboratory. Comparing biological parameters of host insect and parasite in different temperature regimes, we conclude that Diadegma insulare is a more competent parasitoid at lower temperatures.

Host plant shift caused loss of a biosynthetic enzyme in larvae of *Chrysomela lapponica* (Chrysomelinae)

Wilhelm Boland[1], Roy Kirsch[2]

[1]*Max Planck Institute for Chemical Ecology, Germany,* [2]*Max Planck Institute for Chemical Ecology, Germany*

Leaf beetle larvae of the subtribe Chrysomelina are able to exploit secondary metabolites from their host plants to create their own chemical defence. The metabolites are transferred from the larval gut lumen into the defensive secretion for further conversion into the deterrents. The ability for sequestration is already present in deterrent de novo-producing larvae and we demonstrated that exogenous compounds can interfere with the enzymes of the de novo-synthesis. In contrast to the de novo producers, the sequestering species specialized more and more in their host plants, e.g. salicin sequestration requires feeding on salicaceous plants. But in the course of Chrysomelina evolution host shifts occurred from Salicaceae to Betulaceae especially in the species Chrysomela lapponica. These shifts are mirrored in the secretion composition: willow feeders produce manly salicyl aldehyde and birch feeders mainly a cocktail of different butyryl esters. By secretome analyses we revealed that the lack of salicyl aldehyde is due to the loss of the functional enzyme salicyl alcohol oxidase (SAO) which catalyzes the oxidation from the alcohol to the aldehyde. A mutation in the SAO gene is responsible for the loss of SAO activity in the secretion of birch feeders [1]. [1] R. Kirsch, H. Vogel, A. Muck, J.M. Pasteels & W. Boland. Host plant shifts affect a major defense enzyme in Chrysomela lapponica. (2011) Proc. Natl. Acad. Sci., USA., 108, 4897-4901.,

Precise RNAi mediated silencing of metabolic active proteins in defense secretions of juvenile leaf beetles

Antje Burse[1], Peter Rahfeld[2], Rene Roberto Bodemann[3], Magdalena Stock[4], Natalie Wielsch[5], Maritta Kunert[6], Wilhelm Boland[7]

Insects are extraordinarily inventive when it comes to producing defensive compounds for repelling their enemies. To circumvent auto-intoxicative effects, these natural products frequently originate in the epidermis derived exocrine glands. The gland cells produce secretions that are fortified with defensive compounds. Final conversion of non-active precursors into allomones in the secretions enables production of otherwise cytotoxic or instable compounds. For example, the juveniles of the mustard leaf beetle Phaedon cochleariae synthesize bio-active iridoids from non-toxic glucosides in their discharges. We have started with proteome analyses and identified putative proteins from about 25 families in the larval secretions. Next, we have utilized for the first time RNA interference (RNAi) to analyze in-vivo functions of enzymes in biosynthetic pathways in defensive secretions from insects. The iridoid biosynthesis proceeds from 8-hydroxygeraniol-8-O-β-D-glucoside to 8-oxogeranial, and a predicted enzyme with cyclase activity subsequently forms iridoids in the discharges. We have identified a novel protein belonging to the Juvenile Homone Binding Protein superfamily which is involved in the cyclization reaction of monoterpenes made clear by accumulation of the acyclic C10-precursor and simultaneous decrease of the methylcyclopentanoid monoterpenes five days after triggering RNAi. Cyclisation of monoterpenoids is not only known from insects but also plants use this yet enigmatic mechanism for the production of indole alkaloids. By routine usage of RNAi we found additional enzymes involved in the iridoid pathway but also a super oxide dismutase, the silencing of which did not affect the iridoid synthesis. Its function in defensive secretions is subject of current research.

Effects of floral volatiles on plant indirect defense against herbivory: Flowering transgenic torenia plants as a new tool

Takeshi Shimoda
National Agricultural Research Center, Japan

Plants under herbivore attack emit a blend of herbivore-induced plant volatiles (HIPVs) that can attract carnivorous natural enemies of the herbivores. Composition of HIPV blends may be important in plant defense against herbivores, because HIPV blends vary according to plant and herbivore species, and because different HIPV blends can attract different natural enemies. Furthermore, floral volatiles may also affect the effectiveness of plant indirect defense via HIPVs. To test this we I investigated the abilities of transgenic, wishbone flower plants (Torenia hybrida and T. fournieri) infested with spider mites (Tetranychus urticae), emitting a trans-volatile [(E)-β-ocimene] in the presence or absence of endogenous volatiles (natural HIPVs and/or floral volatiles), to attract predatory mites (Phytoseiulus persimilis). P. persimilis females were attracted to natural HIPVs from infested wild-type (wt) plants of T. hybrida but not to those of T. fournieri. The predatory mites preferred novel HIPV blends from infested, transgenic T. hybrida to natural HIPV blends from infested, wt T. hybrida. In contrast, such olfactory discrimination between transgenic and wt plants was not observed in T. fournieri. These results suggest that (E)-β-ocimene enhanced the predator attractiveness of HIPVs blends, but did not so when original HIPVs were non-attractive. Intriguingly, floral volatiles abolished the enhanced attractive ability of T. hybrida transformants, although the floral volatiles themselves did not elicit any attraction or avoidance behavior. These results suggested that the entire blend of plant volatiles including (E)-β-ocimene is important for attracting P. persimilis.

Insect related Interactions at a Multi-trophic Ecosystem

Microorganisms in spider mites (*Tetranychus urticae*) regulate ecological interactions with lima bean plants

Rika Ozawa
Kyoto University, Japan

In response to herbivory, plants emit specific blends of volatiles that attract carnivorous natural enemies of herbivores. These volatiles are called herbivore-induced plant volatiles (HIPVs). HIPVs emitted from two-spotted spider mite (Tetranychus urticae)-infested lima bean plants attract predatory mites (Phytoseiulus persimilis) that prey on the spider mites of genus Tetranychus. Here, we hypothesized that microorganisms in the spider mites were involved in the induction of a specific blend of HIPVs since production of HIPVs induced by the spider mites is involved in salicylic acid (SA)-related signaling pathway in lima bean plants. Microorganisms in the spider mites were divided into two types. One is exo-microbes which exist on the surface or in the gut of the spider mites. The other one is endo-microbes like intercellular symbionts. Recently, it has been reported that intercellular symbionts of insects regulate metabolism and behavior of their hosts. To address the hypothesis, we prepared the following three types of spider mites: exo-microbes-free mites, endo-microbes-free mites and both microbes-free mites. We compared the responses of lima bean plants to damage caused by either type of spider mites. Our results suggest that exo-microbes and endo-microbes in the spider mites are involved in the induction of specific blend of HIPVs through the activation of SA-related signaling pathway in lima bean plants.

Interactions between tomato volatile organic compounds and aphid behaviour

Emilio Guerrieri[1], Pasquale Cascone[2], Luigi Iodice[3], Maria Cristina Digilio[4]

[1]Institute for Plant Protection National Research Council of Italy, Italy, [2]Institute for Plant Protection National Research Council of Italy, Italy, [3]Institute for Plant Protection National Research Council of Italy, Italy, [4]University of Naples, Italy

In the system constituted by tomato, Lycopersicum esculentum (L.), the aphid Macrosiphum euphorbiae (Thomas) and its natural enemy Aphidius ervi (Haliday) it has been showed that the release of volatile organic compounds following aphid attack is responsible for the attractiveness towards the aphid parasitoid in wind tunnel experiments. The main compounds involved in these multitrophic interactions have been characterized and quantified. The possible activity of these compounds in inducing plant direct defences against the aphid M. euphorbiae has been assessed in laboratory tests. The selected VOCs have been applied to uninfested tomato plants either by evaporation or contact and performances of aphids, in terms of plant acceptance, fixation behaviour and aphid development, calculated in standard conditions. The results showed that compounds involved in parasitoid foraging behaviour exhibit a direct effect on aphid performances.

Insect related Interactions at a Multi-trophic Ecosystem

Effects of plant-plant signaling on the colonization and the diversity of arthropods on willow plants

Kinuyo Yoneya[1], Junji Takabayashi[2]

[1]Kyoto University, Japan, [2]Kyoto University, Japan

A plant damaged by herbivores emits a blend of volatiles that is quantitatively and/or qualitatively different from that emitted from an intact conspecific plant. Such volatiles are known to induce defense-related genes in neighboring plants, and consequently enhance their defense against herbivores. This phenomenon is called a plant-plant signaling. Here, we investigated whether a composition of arthropods community on plants is affected by such a plant-plant signaling in nature. To test this, we used a willow plantation in Center of Ecological Research, Kyoto University. We placed pots of (1) intact willow plants, Salix eriocarpa (Salicaceae), exposed to volatiles from conspecific plants infested by leaf beetles Plagiodera versicolora (Coleoptera: Chrysomelidae), (2) willow plants infested by leaf beetles, and (3) intact willow plants (control). We counted the number of arthropods immigrated into plants with different treatments, and the number of leaves infested by herbivores (every day for one week, and then once a month for two month). The timing of immigration of adult leaf beetles, and the composition of arthropods were apparently different among three treatments. Species richness and abundance of arthropods on each treated and control plants were not significantly different. Interestingly, the number of newly emerged sprouts was higher in intact plants exposed to infested plant volatiles than in intact control plants. Such changes would affect arthropods' niches in a local plant community.

Tritrophic interactions among tospovirus, thrips and Arabidopsis

Hiroshi Abe[1], Yasuhiro Tomitaka[2], Shigemi Seo[3], Tamito Sakurai[4], Soichi Kugimiya[5], Takeshi Shimoda[6], Shinya Tsuda[7], Masatomo Kobayashi[8]

[1]RIKEN BioResource Center, Japan, [2]National Agricultural Research Center, Japan, [3]National Institute of Agrobiological Sciences, Japan, [4]National Agricultural Research Center for Tohoku Region, Japan, [5]National Institute for Agro-Environmental Sciences, Japan, [6]National Agricultural Research Center, Japan, [7]National Agricultural Research Center, Japan, [8]RIKEN BioResource Center, Japan

The western flower thrips (Frankliniella occidentalis) is a polyphagous herbivore that causes serious damages on many agricultural plants and also transmits tospoviruses, such as tomato spotted wilt virus (TSWV). Therefore, feeding damage and virus disease caused by thrips attack are serious problems in many countries. Our previous study reported that JA plays an important role to plant response and resistance to thrips, and JA-regulated plant defense decrease thrips performance and preference. In this meeting, we report the analyses of the tritrophic interaction between plants (Arabidopsis plants) and insect vector (western flower thrips), and also plant virus (TSWV). In ecological system, TSWV only move to the new host plants from the infected host plants by insect vector, thrips. We indicate that TSWV infection enhances thrips performance such as feeding activity and increases thrips population density of next generation in Arabidopsis plants. TSWV infection elevated Salicylic acid (SA) contents and induced SA-regulated gene expression. Meanwhile, TSWV infection decreased thrips feeding inducible JA-regulated gene expression. We also indicate that TSWV infection enhances the thrips preference of host plants. Thrips was attracted to the TSWV infected plants, and its attractance was decreased in JA insensitive coi1-1 mutants as compared to WT plants. In addition, SA application to WT plants enhanced this thrips attractance like TSWV infection. Our results suggest the mechanism of virus strategy to attract vector thrips to virus-infected plants taking advantage of antagonistic SA-JA plant defense system.

Contribution of metabolomics and transcriptomics to understanding of plant defense against herbivores

Ivan Galis[1], Ian T. Baldwin[2]
[1]*Okayama University, Japan,* [2]*Max Planck Institute for Chemical Ecology, Germany*

A current progress and accessibility of molecular tools in plants, originally designed for Arabidopsis, allowed practical use of non-model plant species in biological research. Such models provide completely new plant properties and responses to be studied, and offer new ecologically relevant systems to be used in research of natural interactions. In particular, the combination of "omic" tools, such as transcriptomics and metabolomics, provided very useful method for reconstruction of plant signaling pathways and mechanisms that control accumulation of defense metabolites in stressed plants. We provide a practical example of gene expression profiling combined with metabolomics that was used to elucidate the role, biosynthesis and regulation of phenolamide secondary metabolites in defense of Nicotiana attenuata plants against specialist and generalist herbivores. Similar approaches are currently used in Japan to elucidate the innate signaling pathways and defense in monocots including rice plants.

Insect related Interactions at a Multi-trophic Ecosystem

Ecological and evolutionary aspects of indirect interaction webs

Takayuki Ohgushi
Kyoto University, Japan

There is increasing appreciation of ecological consequences of plant-mediated indirect interactions between temporally-, spatially-, and taxonomically-separated species in a context of trait-mediated indirect interactions. In particular, herbivore-induced phenotypes of plants can form indirect interaction webs dominated by not only trophic but also nontrophic and indirect interactions. The phenotypic plasticity of terrestrial plants caused by herbivores is ubiquitous, and thus the plant-centered indirect interaction webs should be prevalent in a wide range of ecosystems. In addition to the species-level interactions, herbivore-induced plant phenotypes can initiate bottom-up trophic cascading effects on the associated community structure and biodiversity, leading to strong community-wide impacts on not only herbivores but also predators. This is because plant phenotypes induced by herbivores have the potential to increase variation and heterogeneity of resources that offer distinct niches for arthropods to coexist. Although such studies are still rare and enable very limited general conclusions, several trends emerge from the existing data. Variation in responses of species richness and abundance of higher trophic levels is largely dependent on the different ways in which plants respond to herbivores. On the other hand, community structure and biodiversity have the potential to indirectly promote trait evolution of community members through changes in plant phenotypic expression, which can impose selection on adaptive traits in insect herbivores. I will highlight the ecological and evolutionary consequences of plant-centered indirect interactions, to bridge the gap between evolutionary and community ecology.

Root feeders and above-ground multi-trophic interactions

Scott Johnson
University of Western Sydney, Australia

It has been recognised for at least 20 years that aboveground and belowground insect herbivores can interact via induced changes to their shared host plants. Plant-mediated mechanisms, including changes in primary and secondary metabolites, are largely thought to underpin these interactions yet few studies have addressed both nutritional and defensive mechanisms simultaneously. Still fewer have attempted to investigate whether such interactions observed in the laboratory translate into changes in field populations of insect herbivores. Using a perennial woody crop, Ribes nigrum (blackcurrant), we have investigated the effects of root herbivory by Otiorhynchus sulcatus (vine weevil) on Cryptomyzus galeopsidis (blackcurrant aphid) and Nematus olfaciens (European blackcurrant sawfly). Performance of aphids increased in the presence of weevils, whereas sawfly performance decreased when sharing a plant with weevils. Increased aphid performance was linked to root herbivore induced increases in the proportion of essential amino acids, whereas poorer sawfly performance resulted from reductions in leaf phosphorus. Aphids induced higher levels of secondary metabolites (specifically phenolics) in roots, but O. sulcatus performance was not adversely affected. Field observations intermittently reflected these interactions; plants with O. sulcatus had fewer sawflies, but higher numbers of aphids. Aphid population build-up increased abundance of natural enemies, which reduced aphid populations to levels equivalent or less than weevil-free plants. To our knowledge, this is the first mechanistic example of plant-mediated effects of root herbivores on different aboveground feeding guilds to be demonstrated in both laboratory and field conditions.

Breaking down plant defenses: Cross-talk mediating facilitation in inter-guild interactions

Roxina Soler Gamborena
Wageningen University, Netherlands

Insect attack changes the physiological status of plants locally and systemically, extending the interaction beyond the two-species pair to the entire community of herbivores and their natural enemies. Most plant-mediated interactions among herbivores seem to result in competition, mediated by induced plant defences which negatively affect not only the initial attacker but also the subsequent ones. I will show a case study where insects from contrasting feeding guilds benefit from the distinct pathways triggered in the plants by them, representing a constraint for the plant when sequentially attacked by aphids and caterpillars. The observed facilitation was asymmetric; caterpillar performance was significantly higher on plants previously attacked by aphids, while aphids were not affected by the presence of caterpillars. The reduced levels of JA and low expression of well-known JA-biosynthesis and JA-regulated genes in systemic leaves of plants attacked by aphids suggest that the facilitation of caterpillar growth and development was mediated by interference with signal-transduction as a result of previous aphid feeding. The facilitation between the herbivores also had consequences for their parasitoids. Overall, both the caterpillar and aphid parasitoid benefited from the facilitation between their hosts. Neonate caterpillars, expected to be highly immobile with limited discrimination ability, proved to be active and selective and preferred to feed on plants with aphids compared to uninfested plants. Aphid infestation therefore turned the plants more susceptible and more attractive to caterpillars, and although counterintuitive, these effects were mediated by plant defenses. How widespread these interactions are, remains to be investigated.

Insect related Interactions at a Multi-trophic Ecosystem

Localized plant induction: Impact on insect fitness and disease resistance

Rana M Sarfraz[1], Jenny S Cory[2], Judith H Myers[3]

[1]University of British Columbia, Canada, [2]Simon Fraser University, Canada, [3]University of British Columbia, Canada

Plants can respond to herbivore damage with phenotypic plastic changes in quality that negatively affect herbivores and prevent subsequent attack. These induced changes may be costly to implement and therefore, it may be more efficient for plants to respond locally, rather than systematically, to herbivore damage. However, studies focusing on localized induced resistance of trees in response to damage by herbivores are scarce. We evaluated the influences of localized induced changes in red alder trees in response to insect feeding on fitness correlates for both female and male western tent caterpillars (Malacosoma californicum pluviale). We infested selected branches of trees with tent caterpillar larvae under field conditions and maintained the neighboring branches as non-infested controls. In the laboratory, larvae were fed leaves from either "induced" or control branches through to the adult emergence. A second cohort of larvae was challenged with a viral pathogen to compare their disease susceptibility on induced vs. intact foliage. Herbivory induced localized responses in damaged branches that reduced leaf quality for growth and development of female western tent caterpillars but not males. However, larval survival was higher, and larvae fed induced leaves were more resistant to disease, than their counterparts on intact leaves. Our findings suggest that localized induced changes in leaf quality could potentially influence populations of tent caterpillars in contradictory ways by reducing their developmental rate and final size and therefore fecundity to a modest degree, while improving their survival and resistance to disease to a larger extent.

Insect related Interactions at a Multi-trophic Ecosystem

Coping with a senescing environment: When insect reveal to plants the secret of eternal youth

David Giron[1], Wilfried Kaiser[2], Melanie Body[3], Franck Dedeine[4], Carlos Lopez-Vaamonde[5], Gaelle Glevarec[6], Jerome Casas[7], Elisabeth Huguet[8]

[1]CNRS - University F. Rabelais, France, [2]CNRS - University F. Rabelais, France, [3]CNRS - University F. Rabelais, France, [4]CNRS - University F. Rabelais, France, [5]INRA - Orleans, France, [6]University F. Rabelais, France, [7]CNRS - University F. Rabelais, France, [8]CNRS - University F. Rabelais, France

Phytophagous insects can be divided in two large groups according to their feeding habit: ectophages feeding externally on plant tissues and endophages living concealed within plant tissues and feeding internally. In spite of a reasonable understanding of the history and origins of the endophagous feeding habit, its evolution and adaptive significance remains unclear. Three major hypotheses have been proposed to explain the endophagous-feeding life history mode: The nutrition hypothesis, the microenvironment hypothesis and the enemy hypothesis. Among these hypotheses, feeding selectively on the most nutritional tissues is undoubtedly considered as a major advantage and this behavior can also be reinforced by manipulating the plant physiology as suggested by the autumnal formation of 'green-islands' around mining caterpillars in yellow leaves. Our results on the Malus domestica/Phyllonorycter blancardella plant-leaf mining system show the ability of leaf-miner insects to manipulate their host plant physiology and to create an "optimal" nutritional micro-environment through cytokinin production by their endosymbiotic partners. This symbiotic association impacts not only nutrient acquisition but also the feeding behavior of leaf miner insects and presumably allowed insects to specialize on specific host-plants. A close investigation at the interspecific level also shows a strong correlation between the presence of the endosymbiotic bacteria Wolbachia and the induction of green-islands suggesting that insect symbionts most probably played a major role in the evolution and/or radiation of the endophagous feeding mode.

Insect related Interactions at a Multi-trophic Ecosystem

Biodiversity drives trait evolution of a community member in an indirect interaction web

Shunsuke Utsumi[1], Yoshino Ando[2], Heikki Roininen[3], Jun-ichi Takahashi[4], Takayuki Ohgushi[5]

[1]University of Tokyo, Japan, [2]Center for Ecological Research, Kyoto University, Japan, [3]University of Eastern Finland, Finland, [4]Kyoto Sangyo University, Japan, [5]Center for Ecological Research, Kyoto University, Japan

The dramatic loss of biodiversity has led researchers to pay increasing attention to the ecological consequences of biodiversity. However, no empirical studies have explicitly addressed a fundamental question how species diversity affects evolutionary responses of organisms in an ecological community, while the tight interactions between ecological community and organism evolution has recently been accepted. Interspecific interactions among herbivores mediated through host plant traits are often critical in herbivorous insect communities, in which prior damage by one herbivore species triggers plant phenotypic changes (e.g., induced defence) influencing growth, survival, and reproduction of another herbivore species sharing same host plants. Because a single plant species can show diverse ways of responses to attack by a wide range of insect herbivores, local species diversity of herbivore communities may affect expression of host plant phenotypes. Herbivorous insects may also locally adapt to such altered host plant phenotypes because insects have quite short lifetime compared to long-lived host plants. We show that difference in local species diversity of herbivore communities leads to divergent trait evolution of the leaf beetle (Plagiodera versicolora). Our field surveys and community-manipulated experiments demonstrated that local species diversity of herbivorous insects determined expression of host plant phenotypes through induced plant responses, resulting in differential selection regime for a feeding trait of the leaf beetle and among-population variation in the trait value. Consequently, herbivore species diversity can control evolutionary trajectories and genetic diversification of community members.

Sequential speciation amplifies biodiversity across a community of insect parasites.

Glen R. Hood[1], Andrew A. Forbes[2], Thomas Powell[3], Scott P. Egan[4], Jeffrey L. Feder[5]

[1]University of Notre Dame, U.S.A., [2]University of Iowa, U.S.A., [3]University of Notre Dame, U.S.A., [4]University of Notre Dame, U.S.A., [5]University of Notre Dame, U.S.A.

The role of species interactions across trophic levels can play a prominent role in fostering biodiversity. Diversity can beget diversity when speciation by one organism drives diversification of associated organisms in adjacent trophic levels, a term coined "sequential speciation". If organisms diverge and create new niches to exploit, catalyzing a "chain reaction" of speciation events, what are the frequency of these events and barriers to gene flow that reinforce diversification? The apple maggot fly, Rhagoletis pomonella (Diptera: Tephritidae), is a textbook example of incipient sympatric speciation. Flies within the R. pomonella complex (apple-, hawthorn-, blueberry- snowberry- and dogwood-infesting) are maintained by differences in eclosion timing, host odor preference and differ in allele frequencies. Recently the Rhagoletis?attacking parasitoid Diachasma alloeum (Hymenoptera: Braconidae), has undergone sequential speciation. Paralleling flies, host-associated populations of parasitoids exhibit differences in allele frequencies, eclosion timing, and odor preference. We tested if sequential speciation was applicable to the remaining members of the Rhagoletis?attacking parasitoid community (Diachasmimirpha mellea and Utetes canaliculatus). Following overwinter, mean eclosion times of both Diachasmimorpha and Utetes differ between host associations paralleling the fruiting phenology of host plants and the eclosion timing of fly hosts. In choice tests both species orients towards natal odors and avoid non-natal odors. Microsatellite loci exhibit consistent site-to-site host-related frequency differences in sympatric populations for both Diachasmimorpha and Utetes. Initial evidence supports sequential speciation across the community of Rhagoletis-attacking parasitoids supporting the hypothesis that sequential speciation is widespread among insect-parasite systems and contributes to the generation of biodiversity.

Do plant-mediated interactions among herbivores affect parasitoid performance and genetic population structure?

Betty Benrey[1], Johnattan Hernandez-Cumplido[2], Jennifer Shlichta[3]
[1]University of Neuchatel, Switzerland, [2]University of Neuchatel, Switzerland, [3]University of Neuchatel, Switzerland

Individuals of different species interact in local communities and can influence each other's fitness both directly or indirectly through intermediaries. This is particularly true for the interactions among plants, insect herbivores and the natural enemies of these herbivores. It is hypothesized that herbivory by one insect will cause changes in a plant that will affect subsequent herbivores and their natural enemies. We test the importance of such effects for a multitrophic system comprising lima bean plants, several species of beetles, and their parasitoids. With this system we investigated the extent to which previous damage on bean leaves and seeds affects the performance and behavior of bruchid beetles and how such effects may cascade upwards to the next trophic level. Beans collected from different wild populations in Mexico were characterized for their content in cyanogenic glycosides. Of these, 4 populations were selected that varied significantly in their concentration of these glycosides and we examined the consequences of changes in plant allelochemistry due to attack by one herbivore on the performance of a second herbivore and its larval parasitoid. To mimic herbivory, we damaged the plants and treated them with jasmonic acid, a hormone implicated in induced defenses against insect herbivores. Our results support the hypothesis that prior induction of plant defenses as a response to damage inflicted to leaves and pods, will alter the suitability of seeds, resulting in a decreased performance of the seed beetle, Zabrotes subfaciatus and its parasitoid, Stenocorse bruchivora.

Insect related Interactions at a Multi-trophic Ecosystem

The role of host-plant and bacteria species in the genetic differentiation of herbivorous insects

Raul F Medina
Texas A&M University, U.S.A.

Host Associated Differentiation (HAD) is the formation of genetically distinct host associated populations. HAD has been invoked to explain the enormous diversity of phytophagous insects. Individual case studies of HAD are interesting but by themselves they are unable to provide clues on the mechanisms that might promote it. Thus, we are studying HAD on several species associated with the same host-plant species pair: Pecan and water hickory (both in the genus Carya). It has been suggested that bacteria in insect herbivores may play a role in HAD by allowing their insect hosts to use different plant species. The objectives of this study were: 1) to assess HAD in 6 Sternorrhyncha species associated with pecan and water hickory and 2) to document if HAD in these Sternorrhyncha corresponded with differences in the composition of their associated bacteria. HAD was determined using AFLPs and Bayesian clustering. Bacterial diversity was characterize through metagenomic analyses using 454 sequencing. HAD was present in 4 out of 6 species tested. Differences in bacterial diversity were found between pecan leaf Phylloxera populations associated with pecan and water hickory. The bacteria, Pantoea agglomerans and Serratia marcescens were absent in the Phylloxera water hickory population whereas both species accounted for more than 69.72% of bacterial abundance in the pecan population. Future studies will assess if the same phenomena occurs in the other Sternorrhyncha species in our system. The Carya system provides a parthenogen rich contrast to the already well characterized Solidago system for the study of HAD.

Host feeding by a gall-inducing insect improves the performance of offspring

Makoto Tokuda[1], Keiichiro Matsukura[2], Shun Kumashiro[3], Masaya Matsumura[4]

[1]Saga University, Japan, [2]Kyushu Okinawa Agricultural Research Center, National Agriculture and Food Research Organization, Japan, [3]Saga University, Japan, [4]Kyushu Okinawa Agricultural Research Center, National Agriculture and Food Research Organization, Japan

The maize orange leafhopper Cicadulina bipunctata (Hemiptera: Cicadellidae) induces galls characterized by stunted growth and severe swelling of leaf veins on various Poaceae. The gall induction by the leafhopper is different from that by other gall-inducing insects in that the galls are induced not on feeding sites but appear on distant, newly developing leaves. In addition, adult C. bipunctata is highly mobile and seldom feed on gall tissue that they have induced. These mean that the gall induction by C. bipunctata is unlikely to contribute to the fitness of the inducer itself. In this study we examined whether manipulation of the host plant by this leafhopper has a subsequent benefit to offspring or not. Adults feeding on maize seedlings caused a partial change in the glucose content and a remarkable change in the accumulation of free amino acids in the gall tissue. Increases in emergence and developmental rates were observed in nymphs feeding on gall tissue induced by prior adult feeding. Such improvements were not evident in nymphs feeding on a C. bipunctata-resistant variety, which rarely displays galls after C. bipunctata feeding, nor on maize seedlings previously foraged by another leafhopper, Psammotettix striatus. The results indicate that gall tissue induced by adult C. bipunctata contribute to better performance of its offspring through improvement of the nutritional components of host plants.

Gall-inducing ability of the maize orange leafhopper *Cicadulina bipunctata* and barley chromosomes related to the resistance and susceptibility to the gall induction

Shun Kumashiro[1], Keiichiro Matsukura[2], Kanako Kawaura[3], Masaya Matsumura[4], Yasunari Ogihara[5], Makoto Tokuda[6]

[1]Saga University, Japan, [2]Kyushu Okinawa Agricultural Research Center, National Agricultur, Japan, [3]Kihara Institute for Biological Research, Yokohama City University, Japan, [4]Kyushu Okinawa Agricultural Research Center, National Agriculture and Food Research Organization, Japan, [5]Kihara Institute for Biological Research, Yokohama City University, Japan, [6]Saga University, Japan

Although many herbivorous insects have the ability to manipulate host plants and induce galls for their own benefit, the mechanism of gall induction by insects is still unknown. This is partially because of the difficulty in establishing mass-rearing systems and performing comparative experiments using galling and non-galling relatives. The maize orange leafhopper, Cicadulina bipunctata (Hemiptera: Cicadellidae) is one of the suitable materials to clarify the mechanism. The leafhopper feeds on various poaceous plants and induces galls characterized by the swelling of leaf veins. A mass-rearing technique has already been established for this leafhopper, and model plants such as rice, wheat, and maize are available for experiments using the leafhopper. Moreover, some host plants such as barley and sorghum does not exhibit any symptoms even when they were fed on by the leafhopper. We examined the effect of barley chromosome addition to wheat on the susceptibility of wheat to C. bipunctata. As a result, barley genes resistant to gall induction were suggested to exist in chromosome 3. In contrast, wheat added barley chromosome 5 promoted gall induction by the leafhopper. In addition, we refer to geographical variations in the gall-inducing ability of the leafhopper and possible selection of non-galling strains.

Progress on gall midges (Diptera: Cecidomyiidae) in China

Kelong Jiao[1], Wenjun Bu[2]

[1]Nankai University, China, [2]Nankai University, China

The Chinese fauna of gall midges (Diptera: Cecidomyiidae) is rich and diverse with over 220 described species with about 180 nominal species in nearly 30-40 genera by our statistics, which are being used to complete one of our recent works: 'Catalog of gall midges (Diptera: Cecidomyiidae) in China: 1917 to 2012', by which many species recorded in older or scatter Chinese papers will come to light. And Chinese studies including our lab's work on advances in taxonomy, phylogeny, physiology, biology, ecology and biological control of gall midges are summarized and introduced to provide a reference for gall midge specialists worldwide further researching.

Host specialisation, diversity and community structure of galling insects in a Papua New Guinean lowland rainforest

Philip Butterill[1], Vojtech Novotny[2]

[1]*University of South Bohemia, Czech Republic,* [2]*University of South Bohemia, Czech Republic*

In the Old World wet tropics, data on gall-forming insect communities are sadly lacking, especially in Afrotropical and Australasian/Oceanian regions. This is the first study to explore gall-forming insect communities and their parasitoid assemblages in a hitherto virtually unknown Papua New Guinean fauna. In order to test galler host specificity, plant phylogenetic indices were used, for the first time in a gall study, across a broad range of tropical rainforest trees. 32 species, representing 22 genera and 15 families of woody plants from all the major angiosperm clades, were sampled over an 8 month period in three lowland rainforest sites around Madang. All but three plant species hosted at least one out of 87 gall morphotypes from 1150 collections. More than 4000 insects were reared. At 2.7 morphotypes per host plant species, these data are comparable with other highly specialised folivores from the region: leaf miners & mesophyll suckers with 2.4 & 0.8 respectively. Initial findings reveal a community dominated by Cecidomyiidae (56%), followed by Hemiptera (26%), and Lepidoptera and Thysanoptera (6%), corresponding most closely with the Indonesian gall fauna. Approximately 96% of galls are estimated to be species specific in this study, the remainder being congeneric feeders. In this tri-trophic system, the host specialisation of the gall-formers' parasitoid assemblages will also be reported and discussed. This study will provide baseline data and pave the way for further investigation of gall-forming insect communities in Papua New Guinea.

Carotenoids, lateral gene transfer and gall midges

Cassidy Cobbs[1], John Stireman[2], Patrick Abbot[3]

[1]Vanderbilt University, U.S.A., [2]Wright State University, U.S.A., [3]Vanderbilt University, U.S.A.

Major features of eukaryote genomes bear the mark of lateral gene transfer (LGT), with endosymbiosis being perhaps the most dramatic signature of large-scale LGT into diverse eukaryotic lineages. We report the discovery a rare example of fungal-to-animal transfer of carotenoid structural genes in gall midges (Diptera: Cecidomyiidae), joining aphids and two-spotted spider mites as the only animals know to possess the capability for in situ biosynthesis of carotenoids. Carotenoids are ubiquitous pigments with far-reaching roles in organismal biology, from central metabolism to communication. We describe patterns of molecular evolution in LGT carotenoids in gall midges with respect to recent studies on other arthropods. We report our progress on tracing the origins of carotenoid acquisition in flies and mapping their acquisition onto major evolutionary and phylogenetic features of the lower Diptera, and discuss how carotenoids may facilitate or inhibit antagonistic and mutualistic interactions in gall midges, and how they have opened new ecological opportunities and have spurred biological diversification in these flies.

Discovery of gall wasps (Hymenoptera: Cynipidae) inducing galls on the strictly Asian subgenus Cyclobalanopsis of the genus *Quercus* (Fagaceae)

Tatsuya Ide[1], Nakatada Wachi[2], Yoshihisa Abe[3]

[1]Biosystematic Laboratory, Kyushu University, Japan, [2]Kyushu University, Japan, [3]Biosystematic Laboratory, Kyushu University, Japan

Of approximately 1,400 cynipid species described to date, about 1,000 species are oak gall wasps belonging to the tribe Cynipini. The host plants of Cynipini belong to the family Fagaceae, primarily the genus Quercus, but also Castanea, Castanopsis, Chrysolepis, and Lithocarpus. The genus Quercus is divided into two subgenera, Quercus and Cyclobalanopsis, with the latter subgenus being restricted to Asia. Despite the extensive distribution of Cyclobalanopsis in Asia, only two species of Andricus (Cynipini) described by Shinji had been recorded as gall inducers on this plant subgenus. However, these two species are actually inquiline gall wasps and were transferred to Ufo of the inquiline tribe Synergini. In 2010, Plagiotrochus masudai Ide, Wachi et Abe, which induces galls on Q. (C.) glauca Thunb., was described from Japan. This is the first definitive description of an oak gall wasp inducing galls on Cyclobalanopsis. After that, some cynipid species associated with Cyclobalanopsis were described from Japan and Taiwan one after another. In Japan, Synergus itoensis Abe, Ide et Wachi (Synergini) was described as a gall-inducing species in the acorns of Q. (C.) glauca. In Taiwan, another species of Plagiotrochus and four species of Cycloneuroterus were described. The latter genus was established in 2011 and named after the host association with Cyclobalanopsis. More recently, three species of Cycloneuroterus were also discovered from Japan. These findings may suggest the potentially diverse cynipid fauna on Cyclobalanopsis in Asia.

Inferring speciation history of the *Andricus mukaigawae* complex (Hymenoptera: Cynipidae) based on nuclear DNA and mitochondrial DNA Data

Nakatada Wachi[1], Yoshihisa Abe[2], Nobuyuki Inomata[3], Hidenori Tachida[4]

[1]Kyushu University, Japan, [2]Kyushu University, Japan, [3]Kyushu University, Japan, [4]Kyushu University, Japan

The Andricus mukaigawae complex of oak gall wasps is composed of two cyclically parthenogenetic species, A. mukaigawae and A. kashiwaphilus, and a parthenogenetic species, A. pseudoflos. The component species differ in their life history, distribution, host plant, karyotype, asexual gall shape, and Wolbachia infection status although little difference is found in the external morphology of asexual adults. Therefore, among oak gall wasps, the A. mukaigawae complex provides a good opportunity for studies on the differences in host plants and in reproductive modes and on their relationship with genetic divergence. In order to understand the genetic relationship of the three species and the origin of asexuality, DNA sequences of one mitochondrial region and nine nuclear regions were investigated in multiple individuals from each of the three species of the complex. The genetic relationship among the three species suggested that a loss of sex had occurred after a host shift. Unexpectedly, two distinct groups were recognized in the parthenogenetic species A. pseudoflos by both the mitochondrial and nuclear DNA data. Gene flow in the nuclear genes from the Wolbachia-uninfected A. kashiwaphilus to infected A. mukaigawae was suggested by a method based on coalescent simulation, whereas gene flow in the mitochondrial genes was in the opposite direction. These findings suggest a possible involvement of Wolbachia infection in the speciation process of the A. mukaigawae complex.

A koinobiont parasitoid manipulates its host cecidomyiid to modify gall morphology to avoid hyperparasitism

Tomohishi Fujii[1], Kazunori Matsuo[2], Junichi Yukawa[3], Yoshihisa Abe[4], Makoto Tokuda[5]

[1]Kyushu university, Japan, [2]Kyushu university, Japan, [3]Kyushu university, Japan, [4]Kyushu university, Japan, [5]Saga university, Japan

Many parasitoids are known to manipulate host behaviour for their own benefit. Parasitoids of gall-inducing cecidomyiids are divided into two groups, early and late parasitoids, according to their parasitic strategies. Early parasitoids are usually koinobionts attacking eggs or first instars before maturation of galls in size. Late parasitoids are idiobionts attacking final instars or pupae by inserting their long ovipositors through the gall wall after maturation of galls. When early and late parasitoids attack the same host individual, only late parasitoid usually survive. Masakimyia pustulae Yukawa & Sunose (Diptera: Cecidomyiidae) induces dimorphic blister-like leaf galls (thick and thin types) on Euonymus japonicus and E. fortunei (Celastraceae). As a result of our survey, one platygastrid early parasitoid, Platygaster sp. (Platygastridae), and two eulophid late parasitoids, Chrysonotomyia sp. and Pnigalio sp. (Eulophidae), were found to parasitize M. pustulae. Among these parasitoids, the late parasitoids were frequently found in thin type galls, but seldom in thick type galls. This result indicates that the thick type gall is adaptive for avoiding parasitism by the late parasitoids. In either type, galls attacked by Platygaster sp. were significantly thicker than unparasitized galls in many localities. In addition, galls attacked by Platygaster sp. were significantly thicker than unparasitized galls from an early stage of gall growth. The percentage parasitism by the late parasitoids was significantly lower in galls attacked by Platygaster sp. than in those not attacked. These results strongly suggest that Platygaster sp. manipulates host behaviour to thicken galls to avoid hyperparasitism by the late parasitoids.

Phylogeny and evolution of gall morphology in eriosomatine aphids

Masakazu Sano[1], Shin-ichi Akimoto[2]

[1]Hokkaido University, Japan, [2]Hokkaido University, Japan

Aphids of the tribe Eriosomatini (Aphididae: Eriosomatinae) are typically associated with the tree genera Ulmus and Zelkova (Urticales: Ulmaceae), on which they induce various types of leaf gall: open leaf rolls, or completely or incompletely closed pouch galls. To elucidate evolutionary change in gall morphology, phylogenetic relationships of the tribe Eriosomatini were inferred using 36 species (28 in the ingroup) and based on 52 morphological characters. Phylogenetic analysis with equal character weighting led to hundreds of most-parsimonious trees, and the strict consensus of these was poorly resolved. However, the successive weighting of characters yielded three most-parsimonious trees, and the strict consensus of these was well resolved. Ancestral reconstruction of gall morphology on the consensus tree suggests that the ancestral gall morphology was open leaf rolls, and that the completely and incompletely closed pouch gall evolved once each from the leaf rolls. The evolutionary transition from open leaf rolls to closed galls was also found in other galling insects, and this convergent evolution in different groups of galling insects suggests that closed galls may have adaptive advantages to the gall formers at the initial stage of its evolution, such as protection against general predators, gall inquilines and unfavorable abiotic conditions. However, it is likely that the restricted space in closed galls limits the number of aphids living inside, leading to the decrease of the number of generations in the galls.

Gall shape variation and host specificity in relation to species identity in a complex galling midge group *Daphnephila* (Diptera: Cecidomyiidae) on *Machilus* spp. (Lauraceae) in Taiwan

Man-Miao Yang[1], Tung-Chuang Chiang[2], Gene-Sheng Tung[3], Makoto Tokuda[4], Junichi Yukawa[5]

[1]National Chung Hsing University, Taiwan, [2]National Chung Hsing University, Taiwan, [3]Taiwan Forestry Research Institute, Taiwan, [4]Saga University, Japan, [5]Kyushu University, Japan

Most of gall-inducers are monophagus or oligophagous, which utilize a narrow spectrum of host plants and organs. Diversity of gall inducers and the specific relationship between galling insects and host plants are considered as a consequence of adaptive radiation. Galls are then often regarded as extension of phenotypes of gall inducers. However, it is unclear to what extend could the shape variation of galls and host specificity represent species identity of gall inducers. Highly diverse group of gall midge Daphnephila spp. (Diptera: Cecidomyiidae) on Machilus (Lauraceae) in Taiwan are used to discuss this issue and multidisciplinary approaches were applied. Thirty-eight morphological species were recognized based on their gall shape, galling position, and host plant information. These galls with similar shapes could be further grouped into 8 series. Samples of gall midges induced similar shape of galls revealed monophyletic relationship based on molecular phylogenies with genetic differentiation ranging from 1.3% to 14.3% between groups. The gall shape series in general reflects the taxonomic status at the category of species or species group, whereas the gall morphospecies may not always reflect the species status. It is necessary to obtain evidences from different aspects and to integrate the overall variation for making correct taxonomic determination for the gall midges and henceforth elucidate their adaptation and sepciation.

Sexual isolation between two intraspecific groups of *Hartigiola faggalli* (Diptera: Cecidomyiidae) that induce different types of leaf gall on *Fagus crenata* (Fagaceae)

Misako Mishima[1], Shinsuke Sato[2], Kiyoshi Tsuda[3], Junichi Yukawa[4]
[1]Kyushu University, Japan, [2]University of Miyazaki, Japan, [3]Minami-satsuma, Kagoshima, Japan, [4]Kyushu University, Japan

Hartigiola faggalli (Diptera: Cecidomyiidae), a species that induces leaf galls on Fagus crenata (Fagaceae), was studied to assess the degree of sexual isolation between intraspecific groups derived from two different gall types. 'Upper type galls' stand on lateral veins of upper leaf surfaces, while 'lower type galls' lie between the lateral veins of lower surfaces. The two groups were not distinguished morphologically but were clearly separated by DNA sequencing. The two gall types coexisted in F. crenata forests and significantly overlapped on host leaves. Hartigiola faggalli is diurnal with one-day adult life span. Emergence, swarming, mating and oviposition occurred successively during particular time slots each day. Each activity was observed almost simultaneously at common sites for the two groups. However, most swarming males flew to females of the same group when responding to female sex pheromone and most mating pairs caught were homogenic. The index of asymmetry (IAPSI) indicated a strong bias to homogenic mating. The female sex pheromone and male sensitivity to the pheromone seemed to differ between the two groups. After mating, females of each group laid eggs correctly on upper or lower surfaces of fresh leaves, respectively. There were a few lower type galls induced on upper leaf surface by the progeny of heterogenic pairs, but sexual isolation apparently existed between the two groups. This may imply that the two groups are possibly at the incipient stage of speciation associated with diversification of pheromone constituents and the development of gall dimorphism.

Olfactory cues in gall midge speciation

Tina Boddum[1], Sharon Rose Hill[2], Bill S Hansson[3], Goran Birgersson[4], Bela Molnar[5], Ylva Hillbur[6]

[1]SLU, Sweden, [2]SLU, Sweden, [3]Max Planck Inst Chem Ecol, Germany, [4]SLU, Sweden, [5]SLU, Sweden, [6]SLU, Sweden

Gall midges (Diptera: Cecidomyiidae) make ideal models for studying the role of olfaction in speciation: they are speciose compared to other dipterans, short lived and non-feeding as adults (1-2 days), their host plant specificity is legendary and they are strongly driven by olfactory cues. In this study we investigated two types of olfactory cues, the pheromone produced by the female to attract the males as well as plant volatiles used by the female to localize a plant for egg legging. With the crucifer specialist Contarinia nasturtii as our model organism we showed that gall midge host specificity is initiated by the olfactory-based host plant choice of the female. We also demonstrated plasticity in host plant choice, plasticity that can be the basis for the fast speciation in the gall midge family. In addition, the role of gall midge pheromones in speciation is discussed by comparing the structures of the pheromones with the phylogeny of gall midges.

Electrophysiological screening to investigate gall midge host plant recognition

Peter Bela Molnar[1], Tina Boddum[2], Goran Birgersson[3], Ylva Hillbur[4], Bill S. Hansson[5]

[1]SLU Swedish University of Agricultural Sciences, Sweden, [2]SLU Swedish University of Agricultural Sciences, Sweden, [3]SLU Swedish University of Agricultural Sciences, Sweden, [4]SLU Swedish University of Agricultural Sciences, Sweden, [5]Max Planck Insitute for Chemical Ecology, Germany

Gall midges constitute an excellent model for investigating the role of olfaction in host choice, host shift and speciation. Gall midges have a high rate of speciation and, reportedly, a high degree of specialization concerning host-plant choice. Most of the more than 5000 gall midge (Diptera: Cecidomyiidae) species are plant feeders and many of them are serious pest. The females use the volatiles emitted by plants to locate a host for oviposition. The differentiation of host plants is likely to be based on specific combinations of common plant volatiles that make up unique combinations. As the adults are short-lived (1-2 days), and the larvae have no or limited capacity to disperse, females are under strong selective pressure to find a suitable oviposition site. In an electrophysiological screening (GC-EAD) we investigate the antennal response profile in several gall midge species to a large number of plant compounds. The selection of compounds represents plant volatiles from known gall midge host plants and other compounds known to be involved in plant insect interactions. So far we have successfully tested the synthetic blend on 10 gall midge species, some of them are closely related, some are distantly related species. Whether gall midges associated with the same host plant use the same or similar set of odors? In addition do closely related species that have different host plant respond to odors common for the different plants?

Ground-dwelling arthropod assemblages following variable retention harvesting: Is green tree retention effective to maintain biodiversity?

Jaime H. Pinzon[1], Stephane Bourassa[2], John R. Spence[3]

[1]University of Alberta, Canada, [2]University of Alberta, Canada, [3]University of Alberta, Canada

Green tree retention (the practice of leaving standing living trees within harvested cut-blocks) is implemented in different parts of the world to maintain post-harvest legacies similar to those remaining after natural disturbances (e.g., wildfire), and to retain forest structure in harvested areas to improve habitat quality. However, it is unknown how much retention is needed to achieve these conservation goals. The Ecosystem Management Emulating Natural Disturbances (EMEND) project was initiated in 1998 as a large scale (ca. 1000 ha) retention harvest experiment in the boreal forest of western Canada to answer this question and to generally assess the effectiveness of green tree retention in this ecosystem. Thus, EMEND aims to test the short and long term effects of various levels of dispersed tree retention (clear-cut to 75% retention) on biodiversity and to determine which of these practices best maintain assemblages most similar to those in stands that originated from natural disturbances (unharvested controls). Ground-dwelling arthropod assemblages have been collected one, two, five and ten years after harvesting, and we present carabid and spider responses five and ten years post-harvest here. Few differences in assemblages were observed between five and ten years post-harvest. In general, lower retention (10-20%) maintains structural features that are lost after clear-cutting, but higher levels are still needed to retain forest specialists, especially in conifer stands in which there was little evidence of faunal recovery ten years post-harvest. We discuss management and conservation implications of these results.

Can intensively managed plantation forests support a diverse arthropod fauna?

Anne Oxbrough[1], Sandra Irwin[2], Thomas C. Kelly[3], John O'Halloran[4]

[1]University College Cork, Ireland, [2]University College Cork, Ireland, [3]University College Cork, Ireland, [4]University College Cork, Ireland

Plantation forests constitute a large proportion of the forest estate in many countries, particularly in the temperate regions of Europe. In addition, large scale deforestation has led to the fragmentation of natural forests within heavily managed agricultural landscapes. In light of this, it is important that the potential of plantations to support a diverse flora and fauna, particularly of forest specialist species, is assessed. We compared arthropod diversity in mixed and single species plantations of non-native conifers to that in native woodlands in forty five stands across Ireland. Spiders and Carabid beetles were sampled with pitfall traps and a range of environmental parameters were measured including vegetation cover, stand structure, soil attributes, and landscape variables such as forest cover. Invertebrate species composition and richness differed between plantations and native woodlands, particularly for key forest-associated species. Responses also differed by taxonomic group. At the stand scale arthropods were related to litter and vegetation cover, whereas large scale variables such as amount of forest cover within 5km were not important. These findings suggest that forest policy aimed at promotion of biodiversity in plantations should support greater diversity of stand structure and tree species composition. The planting of more species of native provenance should also be encouraged.

Tropical trees influence trophic structure but not diversity of litter arthropod communities

David Andres Donoso[1], Mary K. Johnston[2], Natalie A. Clay[3], Michael E. Kaspari[4]

[1]University of Oklahoma, U.S.A., [2]University of Oklahoma, U.S.A., [3]University of Oklahoma, U.S.A., [4]University of Oklahoma, U.S.A.

Litter arthropods in tropical forests are diverse and patchily distributed in space and time. However, litter arthropods are tied to trees providing food and shelter resources necessary for litter arthropod survival. I review basic theory relevant to this interplay between trees and their litter arthropods. The 'tree' hypothesis posits that environments underneath tree canopies are different from those between canopies in ways that shape arthropod distribution. The 'species' hypothesis posits that different plant species maintain distinct litter environments to which arthropod distribution respond. Because trees varies in the amount of litter they produce, one proposed mechanism for tree or species effects would link greater litter volumes to increased predator/prey ratios by increasing arthropod abundance in lower trophic levels. Besides trophic structure, trees can also affect litter assemblages in other ways, the tree specialization hypothesis proposes that tree-driven habitat heterogeneity maintains litter arthropod diversity. In this talk I present results supporting the tree hypothesis. Trophic structure of litter arthropods responded strongly to litter pools, but are agnostic with respect to the tree species producing it. Furthermore, few links between trees species and arthropod species suggest that reasons other than tree diversity likely promote and maintain litter arthropod diversity in the tropics.

Conservation of saproxylic beetles and living tree retention patch size in boreal white spruce forest

Seung-Il Lee[1], John Spence[2], David Langor[3]

[1]University of Alberta, Canada, [2]University of Alberta, Canada, [3]Natural Resources Canada, Canada

Retention of living trees in harvested landscapes has been strongly promoted as a way to conserve biodiversity, and populations of many saproxylic beetles (i.e. beetles that depend on dead or dying wood during some part of their life cycle) are well known to be threatened by forestry practices. Nonetheless, it remains poorly understood how managing the amount and distribution of residual trees in harvest blocks can best meet conservation goals for saproxylic beetle assemblages. To determine if there is a threshold for retention patch size in spruce forest to minimize loss of saproxylic beetles on harvested landscape, three different scales of retention patches (Small: 0.63-0.94 ha, Medium: 1.59-2.97 ha, Large: 3.34-5.93 ha) were selected. Clear-cut and intact forest areas were also chosen as comparisons. Four window traps were set in each patch (2 on girdled trees and 2 on snags). These were installed in both interior and edge to explore edge effects in these sites. Saproxylic beetles were collected every 3 weeks during the snow-free season of 2010, preserved and identified to species level in the laboratory. Our study will provide crucial information about the role of retention patch size for maintaining diverse saproxylic beetle assemblages in view of edge effect.

Soil collembolans of commercial forests plantations of Colombia: Response to plantation age and climatic regime

Adriana Ramos[1], Olga P. Pinzon[2], John Diaz[3]

[1]*Universidad Distrital Francisco Jose de Caldas, Colombia,* [2]*Universidad Distrital Francisco Jose de Caldas, Colombia,* [3]*Universidad Distrital Francisco Jose de Caldas, Colombia*

This study characterized collembolans diversity and relative abundance in forest commercial plantations of Gmelina arborea and Pachira quinata during the humid and dry periods of 2008 in Zambrano - Bolivar (Colombia). Soil collembolans were sampled in 15 plots using pitfall traps and Berlesse funnel extraction from soil and litter. Specimens were sorted and preserved for further determination to family/genera. Relative abundance was used to compare the effect of plantation age and sampling period using ANOVA. Collembolans from to 3 suborders, 7 families and 14 genera were found adding both climatic periods. The Entomobryidae and the Lepidocyrtus genus predominated in both periods in G. melina plantations. Richness index was expressed as dependent on rain regime and plantation age. On the other hand, in P. quinata the most abundant family was Entomobryidae during humid condition and Bourletiellidae during dry condition. collembolan populations were favored in the oldest plantation during the humid period.

Opening the black box: The structure of belowground food webs

Stefan Scheu
Georg August University Goettingen, Germany

Most of ecological research concentrates on the visible world above the ground. From an ecosystem perspective, however, the belowground system is indispensible as most of the biomass produced by plants enters the decomposer system. Further, the belowground system is closely interconnected to the invisible compartment of plants, roots in soil. The decomposer system recycles dead organic matter thereby forming the basis of plant nutrition. However, decomposer biota not only interact with plants by providing mineral nutrients; rather, soil biota interact in various ways with plant roots via altering their physical, chemical and biological environment. These interactions essentially shape plant performance and, via systemic effects, also the aboveground food web. With the advent of novel technologies, such as stable isotope analysis, fatty acid analysis, molecular gut content analysis and the molecular toolbox for analysing plant performance, interactions below the ground are losing mystery and their role in belowground - aboveground interrelationships is being uncovered. The talk will highlight these novel developments by focusing on trophic interactions in belowground food webs and the interrelationships between decomposer animals, plants and the aboveground food web.

Under which conditions does retention harvesting support boreal ground-dwelling forest arthropods?

Matti Jussi Koivula
Finnish Forest Research Institute, Finland

Forestry has impacted North European forests for hundreds of years, but a considerably more intense era begun only some 50 years ago. This intensification has speeded up the rate of extinctions among forest species. Indeed, in Fennoscandia, forestry is considered one reason for the decline of one-third of threatened species. This finding has recently forced forest industries to partly replace clear-cut harvesting with other logging methods, and to change stand structures toward greater heterogeneity in tree composition. Here, I will review the ecological impacts of these actions, with special attention to ground-dwelling arthropods. Responses of arthropods to logging are variable and depend e.g. on species' habitat affinities. At the stand level, retention of 60-70% of the total tree volume will support most ground-dwelling arthropods. The role of structural heterogeneity in supporting forest-arthropod assemblages in managed forests is poorly understood, but recent studies suggest this effect to be significant.

Substrate diversity promotes species diversity in saproxylic beetles

Joakim Hjalten[1], Fredrik Stenbacka[2], Roger Pettersson[3], Therese Johansson[4], Kjell Danell[5], John P. Ball[6], Heloise Gibb[7], Jacek Hilszczanski[8]

[1]SLU, Sweden, [2]SLU, Sweden, [3]SLU, Sweden, [4]SLU, Sweden, [5]SLU, Sweden, [6]SLU, Sweden, [7]La Trobe University, Australia, [8]Forest Research Institute, Poland

Saproxylic (wood living) invertebrates are a major component of forest biodiversity and ecosystem function. At the same time many saproxylic species are disfavoured by forestry. Considerable effort is therefore made to maintain diversity of these species. However, our knowledge on substrate requirement of these species is limited which decreases conservation efficiency. We conducted a large-scale field experiment was to evaluate the relative importance of manipulated microhabitats, i.e. dead wood substrates of spruce (snags, and logs that were burned, inoculated with wood fungi or shaded) for species richness, abundance and assemblage composition of all saproxylic and red-listed saproxylic beetles, separately. Beetles were collected in emergence traps in 30 forest stands. Assemblages of saproxylic beetles differed significantly between substrate types, most pronouncedly between tree species (birch and spruce) and between standing and lying dead wood. Rarefaction curves showed that species richness increased significantly faster with increased substrate diversity. Our results clearly stress the importance of substrate diversity for maintaining saproxylic diversity. It also suggests that some types of variation in substrate characteristics are more important than other but this also depends on which forest type they are placed in. The implication of our results for practical biodiversity management is discussed.

Survey on distribution and species diversity of oak gall wasps (Hymenoptera: Cynipidae) species in West-Azerbaijan, Iran

Abbas Hosseinzadeh[1], Zahra Hashemi Khabir[2], Negar Alioghli[3], Nouraddin Shayesteh[4]

[1]Mahabad Branch, Islamic Azad University, Mahabad, Iran, [2]Agricultural and Natural Resources Research Center of West-Azerbaijan province, Iran, [3]Plant Pests and Diseases Research Laboratory of East-Azerbaijan Province, Sarab, Iran, [4]Mahabad Branch, Islamic Azad University, Mahabad, Iran., Iran

The objective of this study was to determine oak gall wasps diversity in six different locations. So, in this survey, the oak gall wasps were collected from oak forests of West Azerbaijan province during growth seasons (from April to November 2010 and 2011). The galls occurred on oak trees were collected from Pardanan, Mirabad, Nalas, Kavlan, Hamran and Sardasht locations. The number of galls on sampled branches which were 50 cm in diameter and from four cardinal directions on each tree was counted. Species richness of oak gall wasps was estimated and also parameters such as Simpson's index, Shannon's H', and Sorensen similarity quotient were calculated. In this survey, 8 and 30 species of oak gall wasps on oak trees (Quercus infectoria, Q. brantii and Q. libani) were identified in the spring and fall, respectively. The most amount of galls occurred on Q. infectoria. All of the collected gall wasps belong to seven following genera: Andricus, Cynips, Neuroterus, Chilaspis, Pseudoneuroterus, Biorhiza and Aphelonyx. Among these oak gall wasps, 25 species were related to the Andricus genus. The highest amount of Simpson (0.8) and Shannon (2.1) indices were recorded in Pardanan area and also the highest evenness was recorded in Kavlan (0/9). The highest amount of Sorensen similarity was recorded between Pardanan and Sardasht (85 %). The most important point is that the role of oak subspecies and climate of regions should not be ignored in distribution of oak gall wasps.

Changing climate associated with homogenization of forest assemblages of boreal ground beetles (Coleoptera: Carabidae)

John R. Spence[1], Stephane Bourassa[2]

[1]University of Alberta, Canada, [2]University of Alberta, Canada

Carabid assemblages were studied in 1981-82 and 2009-10 using pitfall traps in five habitats in central Alberta, Canada. Traps were run overnight weekly without killing agents during the frost-free season in all years. Overall average catch rate was 39.2% lower in the later period than during 1981-82 (1.62 vs 0.65 beetles/trap/day). Carabid activity was reduced in Lakeside Forest (LS) and Meadow (ME) habitats, but higher in Spruce Forest (SF). Shannon-Weiner diversity (H') (2.73 vs. 2.45) fell between the two study periods, as did overall species numbers (56 vs 34). The 1981-82 catch included 32 species not subsequently collected; 21 (15 only once and 6 less then 5) were relatively rare (≤ 5 specimens), but many had been common earlier, including Pelophila rudis, Elaphrus clairvillei and Platynus mannerheimii. Ten species captured during 2009-10, had not been detected during the earlier sampling period. These included Synuchus impuctatus, Metabletus americanus and the invasive exotic species, Pterostichus melanarius. A Multiple Regression Tree analysis explained 84.4% of variation in the assemblages and identified differences between ME and the four forest habitats, the two sampling periods, and LS vs. SF, Upland Aspen (UA) and Moist Aspen (MA) forests as explaining, respectively, most variation in the assemblages. A Redundancy Analysis suggests that forest carabid assemblages have become more homogeneous in the later years. Weather records from nearby indicate that climate has become warmer and drier during the study period and our data support the hypothesis that climate effects are associated with changes in this local carabid fauna.

Juvenile hormone biosynthetic enzymes as targets for insecticide discovery

Michel Cusson[1], Stephanie E. Sen[2], Tetsuro Shinoda[3]

[1]Natural Resources Canada, Canada, [2]The College of New Jersey, U.S.A., [3]National Institute of Agrobiological Sciences, Japan

Juvenile hormone (JH) plays important roles in insect morphogenesis and reproduction. For this reason, interfering with its biosynthesis has long been considered a promising strategy for the development of target-specific insecticides. Although several inhibitors of JH biosynthetic enzymes have been developed, none have yet been used operationally for the management of insect pests. However, recent progress in the fields of molecular biology and structural bioinformatics has made it possible to clone and characterize key JH biosynthetic enzymes, opening the way to the rational design of highly specific and effective enzyme inhibitors. In addition, the discovery of insect-produced peptides that inhibit JH biosynthesis, the allatostatins, has led to the development of peptide analogs that inhibit JH biosynthesis in vivo, offering an alternative approach for interfering with JH production. This presentation will provide an overview of recent work aimed at the cloning and characterization of JH biosynthetic enzymes and the development of inhibitors of JH biosynthesis.

Plant secondary compounds from *Leucaena leucocephala, Alpinia zerumbet* and *Bidens pilosa*

Shinkichi Tawata
University of the Ryukyus, Japan

The search for botanical insecticides has increased recently due to the adverse effects of synthetic insecticides and the eco-toxicological properties. Risks and problems associated with the use of chemicals lead to increasingly stringent environmental regulation of pesticides, and hence, the need of developing safer and eco-friendly alternatives that have potentiality to replace synthetic insecticides is imperative. The plants Alpinia zerumbet, Leucaena luecocephala and Bidens pilosa are extensively found in Okinawan islands. Several compounds from Alpinia spp. have been identified to have insecticidal activities against Drosophila, Spodoptera, Sitophilus, Tribolium, etc. We have previously isolated dihyro-5,6-dehydrokawain (DDK) from alpinia and showed the insecticidal activity of DDK-derivatives against Coptotermes formosanus. Furthermore, the plant Leucaena contains a non-proteinogenic amino acid, mimosine, which have been reported to possess insecticidal activity. Besides, proteinase inhibitors from Leucaena have also been identified as a bio-insecticide. Studies regarding utilization of B. pilosa as a natural source of insecticides are very scarce, however, several studies on this plant has clearly indicated its possibility to be a bio-insecticide. Therefore, further researches in these plants regarding the development of natural insecticides are very imperative. Since our laboratory always focuses on total utilization of Okinawan plants, we are continuing our research in, firstly, identifying the potent natural insecticides from these plants and secondly, synthesizing derivatives of these natural compounds to develop more potent, yet safer, insecticides.

Design of molting hormone agonists

Yoshiaki Nakagawa
Kyoto University, Japan

20-Hydroxyecdsysone (20E) regulates the insect molting, and the disruption of the action of 20E leads insects to death. It has been thought that 20E-like compounds have been thought to be insect growth regulators (IGRs), and diacylhydrazine (DAH)-type compounds came into the pesticide field two decades ago. To date, five DAHs (tebufenozide, methoxyfenozide, chromafenozide, halofenozide, and fefenozide) are commercialized as insecticides, but these DAHa besides halofenozide are specific to Lepidoptera. This is due to the fact that the binding site of DAH is slightly different from that of 20-hydroxyecdysone that is commonly used as a molting hormone in insect and other Ecdysozoa. Therefore, the compounds that bind to the 20E-binding site of EcR are able to be IGRs with broad insecticidal spectrum. We recently performed the ligand-based virtual (in silico) screening to find novel ecdysone agonists using the OpenEye software and in-house program. As the template ligand molecule ponasterone A (PoA) that is more potent than 20E was used. Three million compounds were screened down to 20,000 compounds, then to 237 compounds based on QSARs derived for PoA analogs. Finally 24 compounds were submitted to the cell-based binding assay using Sf-9 and BCIRL-Lepd-SL1 cells. Three novel compounds specifically bound to the molting hormone receptor of both cell lines but did not show the agonistic activity at 100 μM. It was demonstrated that these compounds reasonably bound to the ligand binding domain of the molting hormone receptor for Sf-9, which is modeled from the crystal structure of Heliothis virescence EcR.

Ligand-gated chloride channels: Important sites for developing novel insecticides

Yoshihisa Ozoe
Shimane University, Japan

The nervous system function is maintained by the balance of the cell-to-cell communication mediated by the excitatory and inhibitory neurotransmitters at synapses. In insects, acetylcholine plays an important role as an excitatory transmitter, while γ-aminobutyrate (GABA) serves as a major inhibitory transmitter. Glutamate functions as both excitatory and inhibitory transmitters in insects. Excitatory transmitters open cation channels for transmembrane signaling, whereas inhibitory transmitters open anion (chloride) channels. Inhibition or excessive stimulation of these channels causes lethality in insects. Therefore, these channels are critical targets for insecticides and parasiticides. The first generation of insecticides that target the chloride channels include γ-BHC and cyclodienes, which act as negative allosteric modulators (NAMs), and it can be said that the second generation insecticides are phenylpyrazoles with a similar NAM activity. Recently, we reported that the antiparasitic isoxazoline A1443 uniquely blocks GABA- and glutamate-gated chloride channels (GluCls) with selectivity to the former channel. A1443 acts at a site distinct from the site for the first and second generations of NAM insecticides. A1443 can be categorized as the third generation of NAMs that target GABA-gated chloride channels. In contrast to NAMs, insecticidal and antiparasitic macrolides activate GluCls as positive allosteric modulators. These macrolides have unique site(s) in GluCls. Another important ligand binding site is the orthosteric site, which is the site for agonists and competitive antagonists. Design and synthesis of chemicals that fit into these sites will lead to the development of the next generation of pest control chemicals.

Genetic mapping of etoxazole resistance mutations in *Tetranychus urticae* provides new insights in the mode of action of chitin synthesis inhibitors

Thomas Van Leeuwen[1], Peter Demaeght[2], Edward J Osborne[3], Luc Tirry[4], Richard M Clark[5]

[1]Ghent University, Belgium, [2]Ghent University, Belgium, [3]University of Utah, U.S.A., [4]Ghent University, Belgium, [5]University of Utah, U.S.A.

We developed a population, multi-generational bulk segregant analysis (BSA) mapping method to identify etoxazole target-site resistance mutations and thus the molecular target for the acaricide etoxazole in the spider mite, Tetranychus urticae, an important global pest. Etoxazole represents one of several compound classes that act as potent chitin biosynthesis inhibitors, and that are of great agricultural importance for the control of arthropod populations. We identified a nonsynonymous variant in the major T. urticae chitin synthase enzyme that confers target-site resistance to etoxazole, suggesting a direct interaction between etoxazole and chitin synthase. Identification of the target-site of a chitin synthase inhibitor is important to fully exploit chemical structures. Intriguingly, the nature of the CHS1 mutation underlying resistance is potentially informative as to why the exact mode of action of arthropod chitin biosynthesis inhibitors have remained elusive for decades: the target site mutation suggests that inhibition acts on a non-catalytic (but essential) function of CHS1 complexes.

Frequencies of the M918I, T929I and L1014F mutations in the sodium channel of the diamondback moth in China, Thailand and Japan

Shoji Sonoda
Okayama University, Japan

In addition to the allele frequencies of the L1014F and T929I mutations which are involved in nerve-insensitive resistance to a pyrethroid in the diamondback moth, those of the M918I mutation were examined using field strains obtained in China, Thailand, and Japan. Results show that the resistance allele frequencies at the L1014F site were 89%-100%, 97%-100% and 65%-100%, respectively, for strains in China, Thailand, and Japan. The respective allele frequencies at the T929I site were 86%-100%, 70%-97% and 58%-84% for Chinese, Thai, and Japanese strains. With low frequencies up to 27%, M918I was found in Japan and China, but not in Thailand. The strain homozygous for the M918I and L1014F mutations was established and its resistance level to a pyrethroid was examined. The strain lacks a portion of the sodium channel gene corresponding to the 3´ portion of exon 18a, intron 18, and the 5´ portion of exon 18b. Nevertheless, the strain showed a similar level of resistance to that which was homozygous for the T929I and L1014F mutations.

Resistance to diamide insecticides in the diamondback moth in China

Yidong Wu[1], Xingliang Wang[2], Yihua Yang[3], Shuwen Wu[4]

[1]Nanjing Agricultural University, China, [2]Nanjing Agricultural University, China, [3]Nanjing Agricultural University, China, [4]Nanjing Agricultural University, China

Chlorantraniliprole is the first commercial insecticide from a new class of chemistry, the anthranilic diamides. Chlorantraniliprole provides an effective alternative insecticide for control of Plutella xylostella populations resistant to other insecticides. Baseline susceptibility to chlorantraniliprole for P. xylostella was surveyed from 16 geographical populations sampled from China during 2008-2009, and the median lethal concentrations (LC50s) varied among populations from 1.8- to 8.9-fold higher than the LC50 of a susceptible strain (Roth). Twenty field populations of P. xylostella sampled in 2010-2011 from China were tested with laboratory bioassays to determine if resistance to chlorantraniliprole had evolved in the field. The LC50s of the 14 populations from northern China ranged from 1.7- to 5.4-fold compared with the LC50 of Roth, which indicates these populations remain susceptible to chlorantraniliprole. However, the LC50s of the 6 populations from southern China (Guangdong Province) were 2.6-, 12-, 18-, 81-, 140-, and 2,000-fold higher than the LC50 of Roth. The results showed that high levels of resistance to chlorantraniliprole had evolved in field populations from Guangdong Province of southern China. Cross resistance, inheritance mode and resistance mechanisms of the field-evolved resistance to chlorantraniliprole were preliminarily characterized. Intensive use and misuse of chlorantraniliprole may be responsible for the rapid evolution of high-level resistance in P. xylostella from southern China. The implementation of resistance monitoring plans and resistance management strategies is urgently needed in China to preserve susceptibility to chlorantraniliprole in P. xylostella.

Dynamics of insecticide resistance in the peach-potato aphid, *Myzus persicae*

Ian Denholm[1], Diana Cox[2], Stephen Foster[3], Martin Williamson[4]

[1]Rothamsted Research, United Kingdom, [2]Rothamsted Research, United Kingdom, [3]Rothamsted Research, United Kingdom, [4]Rothamsted Research, United Kingdom

In the UK and elsewhere in northern Europe, Myzus persicae is largely anholocyclic, consisting of relative few clonal lineages each with a characteristic and constant suite of resistance genotypes. As a result, the dynamics of resistance genes must reflect the outcome of inter-clonal selection across the genome as a whole as much as selection acting at individual loci. The congealing and persistence of such multi-locus and co-adapted genotypes within clones has interesting and important implications for tactics aimed at combating established and new resistance mechanisms. On the one hand, it should buffer resistance genes from the temporal and spatial fluctuations in frequency that reflect the interplay of fitness costs and insecticide use and which often occur in sexually-outcrossing organisms. More controversially, it could also buffer against the rapid invasion of novel resistance genes, whose success depends not only on their appearance in a new area but also on their rapid incorporation through recombination into locally-adapted gene pools. These ideas will be discussed with reference to long-term aphid resistance monitoring data from the UK and a prognosis for the northwards spread of a novel target-site based mechanism of resistance to neonicotinoid insecticides that is currently confined to southern Europe.

Mechanisms of resistance to neonicotinoid insecticides in the peach-potato aphid, *Myzus persicae*

Alin Mirel Puinean[1], Martin Williamson[2], Stephen Foster[3], Lin Field[4], Ian Denholm[5], Neil Millar[6], Chris Bass[7]

[1]University College London, United Kingdom, [2]Rothamsted Research, United Kingdom, [3]Rothamsted Research, United Kingdom, [4]Rothamsted Research, United Kingdom, [5]Rothamsted Research, United Kingdom, [6]University College London, United Kingdom, [7]Rothamsted Research, United Kingdom

Myzus persicae is a serious pest on crops all over the world causing damage through feeding and pathogen transmission. It has a long history of developing resistance to most insecticides used for its control. The neonicotinoids, an important class of insecticides that target specific receptors in the insect's nervous system have been used effectively to control M. persicae for over two decades. However, intensive reliance on these compounds has led to a gradual increase in resistance, culminating with the loss of field effectiveness in some fruit orchards in southern Europe. Research into the mechanisms underlying resistance to neonicotinoids in M. persicae showed that cytochrome P450-mediated detoxification together with possible additional mechanisms like slower cuticular penetration account for low levels of resistance that do not compromise field control. However, the most potent resistance is conferred by a point mutation in the nicotinic acetylcholine receptor (nAChR) - the neonicotinoid target site. Evidence for the proposed mechanisms of resistance will be presented in selected M. persicae clones and the effect of the identified target-site mutation discussed in the context of previous studies on neonicotinoid insecticide selectivity for the insect nAChR.

Neonicotinoid resistant *Myzus persicae* demonstrate an increased ability to locate untreated plant tissue compared to a susceptible clone

Lucy Fray[1], Eddie McIndoe[2], Russell Slater[3], Glen Powell[4], Simon Leather[5], Rob Lind[6]

[1]Imperial College London, South Kensington Campus, London, SW7 2AZ., United Kingdom, [2]Syngenta, Jealott's Hill International Research Centre, United Kingdom, [3]Syngenta Crop Protection, United Kingdom, [4]Imperial College London., United Kingdom, [5]Imperial College London, United Kingdom, [6]Syngenta, Jealott's Hill International Research Centre, United Kingdom

The peach potato aphid Myzus persicae is a major agricultural pest with the ability to transmit over 100 plant viruses to a wide range of crops. Control relies greatly upon treatment with neonicotinoid insecticides e.g. thiamethoxam. In 2009 the FRC clone was discovered on peach in France. This clone exhibits between 255-1679 fold resistance to current neonicotinoids previously linked to metabolic and target site resistance. It is possible that dispersal behaviour may enhance the resistance of an insect by causing it to remain upon treated plants for a shorter length of time and so ingest a lower dose of insecticide. This study investigated if this was the case with the FRC clone, and is the first to compare the dispersal behaviour of aphid clones of the same species with differing levels of resistance to insecticides. The dispersal behaviour of the FRC clone was compared with that of a clone of lower neonicotinoid resistance, 5191A, and the susceptible clone US1L. The data highlighted several differences in dispersal behaviour between these clones. Most importantly, the FRC clone exhibited an increased ability to locate untreated areas when presented with an environment consisting of both thiamethoxam-treated and untreated plant tissue. This behaviour was not seen in the other clones, suggesting that altered dispersal behaviour may partially account for the high level of neonicotinoid resistance exhibited by the FRC clone. Since the dispersal of aphid vectors is key to the transmission of viruses across crop fields, this has implications for current crop protection practice.

Activities of the Insecticide Resistance Action Committee (IRAC), with particular emphasis on Asia

Ralf Nauen
IRAC International, c/o Bayer CropScience, Monheim, Germany

The Insecticide Resistance Action Committee (IRAC), formed in 1984 and a subgroup of CropLife International, currently consists of 14 member companies and is committed to ensuring the sustained effectiveness of the industry's products. The mission of IRAC is thus to facilitate communication and education on insecticide resistance and to promote the development of resistance management strategies in crop protection and non-agricultural insecticide uses to support sustainable agriculture, improved public health and enhanced professional product use. IRAC has a role in initiating key research and extension projects as well as seeking to improve the measurement and understanding of resistance development. In addition, IRAC International supports IRAC country groups to devise and promote effective local solutions to insecticide resistance problems. IRAC maintains and promotes the global classification of modes of insecticide action, and using this information it is possible to construct appropriate IRM strategies using a range of available products. Depending on the insect, it is possible to use insecticides which act at alternative target sites or which are resisted in different ways, thus maintaining the efficacy of the various insecticidal components of a crop protection strategy. The overall aim of this effort is to keep all classes of insecticides and acaricides as viable control options and to protect the long-term viability of insecticide use.

Identification of imidacloprid resistance mechanism in the cotton aphid, *Aphis gossypii* (Hemiptera: Aphididae)

Ju Il Kim[1], Yoo Ree Joo[2], Min Kwon[3], Jeom Soon Kim[4], Young Gyu Lee[5], Si Yong Kim[6], Si Hyeock Lee[7]

[1]Highland Agriculture Research Center, NICS, RDA, Republic of Korea, [2]Highland Agriculture Research Center, NICS, RDA, Republic of Korea, [3]Highland Agriculture Research Center, NICS, RDA, Republic of Korea, [4]Highland Agriculture Research Center, NICS, RDA, Republic of Korea, [5]Highland Agriculture Research Center, NICS, RDA, Republic of Korea, [6]Crop Protection Research Team, Dongbu Hannong Co., Ltd, Republic of Korea, [7]Seoul National University, Republic of Korea

The cotton aphid, Aphis gossypii (Glover), is also one of the most serious pest in various vegetables. Neonicotinoid insecticides exhibit niceish insecticidal activity against Myzus persicae in Korea. However, some field populations of A. gossypii showed high resistant against neonicotinoid. The imidacloprid-resistant strain (IR) selected from that populations and that was 278 folds more resistant to imidacloprid compared to a susceptible strain (S) as judged by LC50 values. The IR showed cross resistances to other neonicotinoid insecticides. To identify differentially expressed genes in IR, comparative transcriptome analyses based on GS-FLX were conducted using total RNAs extracted from both IR and S strains. Seven ATP-binding cassette (ABC) transporter genes were newly identified in A. gossypii, among which only ABCC9 gene was highly expressed in IR. Therefore, this ABCC subfamily, a member of the MRP subfamily which is involved in multi-drug resistance, could be one of the factors associated imidacloprid resistance in A. gossypii. Comparison of the nucleotide sequence of six nicotinic acetylcholine receptor (nAChR) subunit (alpha 1-5, beta 1) genes from S and IR strain revealed a point mutation in the loop D region of the nAChR beta 1 subunit of the IR, causing an arginine to threonine substitution (R81T). These mechanisms also reported in M. persicae and this amino acid change confers a vertebrate-like character to the insect nAChR and results in reduced sensitivity to neonicotinoids. This is the first investigation of imidacloprid resistance mechanism in A. gossypii and also can apply to manage A. gossypii resistant populations in field.

Resistance situation against neonicotinoid insecticides in the brown planthopper, *Nilaparvata lugens*

Masaya Matsumura[1], Sachiyo Sanada-Morimura[2], Akira Otuka[3]

[1]*NARO Kyushu Okinawa Agricultural Research Center, Japan,* [2]*NARO Kyushu Okinawa Agricultural Research Center, Japan,* [3]*NARO Kyushu Okinawa Agricultural Research Center, Japan*

Insecticide resistance against imidacloprid has developed in the brown planthopper Nilaparvata lugens (Stal) in many Asian countries since 2005. The susceptibility of BPH against five neonicotinoid insecticides (imidacloprid, thiamethoxam, dinotefuran, clothianidin, and nitenpyram) were monitored by topical application method from 2006 to 2010 in East Asia (Japan, China, and Taiwan), Northern Vietnam (the source area of the BPH migration to East Asia), and Southern Vietnam (Mekong delta). The LD50 values of BPH against imidacloprid increased from 2006 to 2009, and have slightly decreased in 2010 in all the areas tested. The peak values of the LD50's were 80μg/g both in East Asia and Northern Vietnam. The patterns of annual change in the LD50 values against imidacloprid was quite similar between East Asia and Northern Vietnam, suggesting that the resistance situation in East Asia to which the planthoppers immigrated reflects the situation in the source area (Northern Vietnam). In contrast, the LD50 values in Southern Vietnam were 150-250μg/g, suggesting that BPH resistance to the imidacloprid is on the rise in the Mekong delta. In the Mekong delta, the LD50 values of thiamethoxam and clothianidin were 10μg/g at a maximum, but those in dinotefuran and nitenpyram were 2μg/g. A significant correlation was found in the LD50 values between imidacloprid and the other four neonicotinoids. Speamann's rank correlation coefficient was high in the two combinations, i.e., imidacloprid v.s. thiamethoxam and imidacloprid v.s. clothianidin.

Neonicotinoid and spinosad resistance in *Musca domestica*; from bioassay to transcriptome

Michael Kristensen[1], Mette D K Markussen[2], Dorte Højland[3]

[1]Aarhus University, Denmark, [2]Aarhus University, Denmark, [3]Aarhus University, Denmark

The molecular mechanisms responsible for resistance are important in responce to alterations in susceptibility in insect pest populations and to develop strategies to prevent development of resistance. Neonicotinoids and spinosad were introduced for insect control within the last decade and play in many countries an essential role for the control of house flies and other insects. We have identified neonicotinoid- and spinosad-resistant housefly strains questioning the future use of these insecticides targeting the neural nicotinic acetylcholine receptor. Females of a multi-resistant field population were spinosad-resistant, whereas male house flies of this strain were susceptible. Selection of this population with two neonicotinoids, spinosad and fipronil led to four strains with an interesting pattern of cross-resistance. We present differences in expression of nACh-receptor subunit Mdα2 as well as gender specific differences between expression of CYP6D3, CYP6A1, CYP6D1, CYP6G4, CYP6A36, CYP6A37, CYP12A1 and CYP12A2 and elucidate their response to sublethal doses of spinosad and phenobarbital. Comparison of transcriptome (400.000 sequences averaging 250 bp) from insecticide-resistant and susceptible house fly strains revealed interesting difference CYP6D1 from resistant and susceptible transcriptome.

Dynamics and mechanisms of insecticide resistance in European populations of the pollen beetle, *Meligethes aeneus*

Christoph T Zimmer[1], Ralf Nauen[2]

[1]*University of Hohenheim, Germany,* [2]*Bayer CropScience AG, Germany*

Pollen beetle, Meligethes aeneus F. (Coleoptera: Nitidulidae) is a major pest in European oilseed rape. Winter oilseed rape is cultivated on several million hectares in Europe. The continuous use of pyrethroids resulted in high selection pressure and subsequent development of resistance. Pyrethroid resistance in pollen beetle is now widespread in many European countries. A resistance monitoring using an adult vial test revealed high levels of resistance to numerous pyrethroids. Detailed cross-resistance and synergism studies were carried out using the same assay design. Synergism experiments revealed a high synergistic potential of piperonyl butoxide in vivo. A PCR approach with degenerate primers for conserved regions of CYP6 family revealed 13 CYP-like sequences from pollen beetle cDNA pools. Evaluation of expression levels by RT-qPCR showed that one gene (CYP6BQ23) is highly overexpressed (>200 fold) in resistant populations. Recombinant expression of CYP6BQ23 using a baculovirus expression system with a Spodoptera frugiperda cell line confirmed a significant role of this CYP for pyrethroid resistance, and the forming of 4'OH-deltamethrin. Elevated expression of CYP6BQ23 is correlated with resistance levels in pyrethroid-resistant populations throughout Europe. In contrast a second mechanism, i.e. target-site resistance conferred by an L1014F mutation in the para-orthologous voltage-gated sodium channel known as kdr (knock down resistance) seems to be restricted to populations from northern Europe, especially Denmark and Sweden. For further investigations of cross-resistance patterns and the characterization of the pyrethroid target site the coding sequence of the para-orthologous gene was isolated.

A nicotinic acetylcholine receptor point mutation associated with resistance to spinosad in western flower thrips (*Frankliniella occidentalis*)

Neil S. Millar[1], Alin M. Puinean[2], Stuart J. Lansdell[3], Toby Collins[4], Pablo Bielza[5]

[1]University College London, United Kingdom, [2]University College London, United Kingdom, [3]University College London, United Kingdom, [4]University College London, United Kingdom, [5]Universidad Politecnica de Cartagena, Spain

High levels of resistance to spinosad, a macrocyclic lactone insecticide, have been reported previously in western flower thrips, Frankliniella occidentalis, an economically important insect pest of vegetables, fruit and ornamental crops. We have cloned the nicotinic acetylcholine receptor (nAChR) α6 subunit from F. occidentalis (Foα6) and compared the nucleotide sequence of Foα6 from susceptible and spinosad-resistant insect populations (MLFOM and R1S, respectively). A single nucleotide change has been identified in Foα6, resulting in the replacement of an amino acid in the transmembrane domain of Foα6. Whilst there is no direct evidence identifying the location of the spinosad binding site, the analogous amino acid in the C. elegans glutamate-gated chloride channel lies in close proximity to the known binding site of ivermectin, another macrocyclic lactone pesticide. The functional consequences of the resistance-associated mutation have been examined in the human nAChR α7 subunit. Introduction of an analogous mutation in α7 abolishes the modulatory effects of spinosad whilst having no significant effect upon activation by acetylcholine. In addition, in radioligand competition binding studies, spinosad did not displace binding of bungarotoxin to the α7 nAChR. These data are consistent with spinosad having an allosteric mechanism of action.

Risk assessment of genetically-modified maize debris on stream-inhabiting arthropods

William O. Lamp[1], Galen P. Dively[2], Christopher M. Swan[3]

[1]University of Maryland, U.S.A., [2]University of Maryland, College Park, MD, U.S.A., [3]University of Maryland, U.S.A.

We assessed risk of Bt maize debris on stream arthropods based on exposure and non-target effects, with a focus on the movement of senesced crop debris into streams. For exposure, we measured debris movement into streams and the persistence of Bt bioactivity with time. For effect, we evaluated Bt and non-Bt near-isoline senesced leaf tissue on aquatic arthropods. In addition, we measured decomposition and colonization rates of leaf tissue in streams. From our results on maize modified with the Cry1Ab gene, we found rapid loss of Bt bioactivity with environmental exposure as well as a delay in the movement of leaf debris into streams, suggesting a lack of significant exposure of Bt to stream organisms. Our effect studies demonstrated no harm to trichopteran leaf-shredding species, while a tipulid crane fly and an isopod exhibited reduced performance on one Bt variety. In addition, decomposition and colonization rates varied among streams, but were not related to Bt. Our results provide evidence that adverse effects to aquatic non-target shredders involve complex interactions arising from plant genetics and environment which cannot be ascribed to the presence of Cry1Ab proteins. More recently, our results with stacked varieties show significantly increased persistence of Bt in maize tissue, extending exposure for several months after harvest. Thus, the balance of exposure and non-target effects in risk analysis may be altered with the deployment of new varieties, placing more value on tests of the potential non-target effect of Bt maize on stream invertebrates.

Genetically modified crops and aquatic ecosystems: Considerations for environmental risk assessment and non-target organism testing

Keri Carstens
Pioneer, DuPont, U.S.A.

Environmental risk assessments (ERA) support regulatory decisions for the commercial cultivation of genetically modified (GM) crops. The ERA for terrestrial agroecosystems is well-developed, whereas guidance for ERA of GM crops in aquatic ecosystems is not as well-defined. The purpose of this document is to demonstrate how comprehensive problem formulation can be used to develop a conceptual model and to identify potential exposure pathways, using Bacillus thuringiensis (Bt) maize as a case study. Within problem formulation, the insecticidal trait, the crop, the receiving environment, and protection goals were characterized, and a conceptual model was developed to identify routes through which aquatic organisms may be exposed to insecticidal proteins in maize tissue. Following a tiered approach for exposure assessment, worst-case exposures were estimated using standardized models, and factors mitigating exposure were described. Based on exposure estimates, shredders were identified as the functional group most likely to be exposed to insecticidal proteins. However, even using worst-case assumptions, the exposure of shredders to Bt maize was low and studies supporting the current risk assessments were deemed adequate. Determining if early tier toxicity studies are necessary to inform the risk assessment for a specific GM crop should be done on a case-by-case basis, and should be guided by thorough problem formulation and exposure assessment. The processes used to develop the Bt maize case study are intended to serve as a model for performing risk assessments on future traits and crops.

Non-target effects of GM crops: A global synthesis

Steven E Naranjo[1], Joerg Romeis[2]
[1]*Arid-Land Agricultural Research Center, U.S.A.,* [2]*Agroscope Reckenholz-Tanikon Research Station ART, Switzerland*

Despite the wide scale cultivation of GM crops globally and the large number of non-target studies that have been completed over the past 15-20 years in support of risk assessment, there remain concerns about the unexpected effects of the technology on the environment. A number of reviews and several meta-analyses have been conducted in an attempt to summarize and synthesize the extant literature. In general, these summaries and analyses have demonstrated a general lack of effect on non-target abundance in the field and on various measures of their biology in the laboratory. However, many additional studies have been published since these synthetic studies were completed and additional new guidance has become available that help to better assess the veracity of all non-target studies currently available in the literature. Here we will re-assess the world literature and quantify non-target effects through meta-analyses. Attention will be placed on non-target abundance and diversity in the field and on life history in the laboratory. Special focus will be placed on natural enemies important in biological control by examining effects on abundance, biology and biological control function. Finally, we will further examine the connection between laboratory and field results in order to inform the tier-testing system used by many regulatory authorities.

Evaluation of Genuity® Bollgard III® cotton effects on non-target organisms

Andrew Davies[1], Mary Whitehouse[2], Lewis Wilson[3], Geoff Baker[4]
[1]CSIRO, Australia, [2]CSIRO, Australia, [3]CSIRO, Australia, [4]CSIRO, Australia

The Australian cotton industry has almost universally adopted Bt-transgenic cotton varieties (currently Bollgard II® expressing Cry1Ac and Cry2Ab) primarily due to their effective suppression of target Helicoverpa pests. Resistance development in Helicoverpa was a recognised threat prior to the release of these technologies, and a pre-emptive resistance management plan developed and implemented. To further mitigate the risk of resistance in Helicoverpa increasing, Monsanto has developed Genuity® Bollgard III®, which expresses an additional insecticidal protein (VIP3A). In transgenic cotton varieties, VIP3A alone demonstrates relatively few effects on non-target organisms (Whitehouse et al. 2007). Extensive worldwide research on Cry proteins has demonstrated limited to no direct or indirect toxicity to non-target organisms. Likewise, assessments within Bt-crops at the community level demonstrate few consistent non-target effects. However, the combined expression of VIP3A, Cry1Ac and Cry2Ab in Bollgard III® may pose a risk to non-target organisms. Here we present the latest findings from field assessments of Bollgard III® non-target effects in Australia. To date, results demonstrate that the arthropod assemblage associated with Bollgard III® is not significantly different to that of Bollgard II®. Significant seasonal divergence between arthropod assemblages associated with Bollgard III® and non-Bt cotton is largely driven by increasingly disparate pest larval densities. At present, we believe it is unlikely that Bollgard III® will affect non-target organisms in a different manner to currently utilized Bt-transgenic varieties. Evidence suggests the commercial release of Bollgard III® would help ensure the ongoing effectiveness of Bt-transgenics on which the Australian cotton industry is almost exclusively reliant.

Bioassay of cry1 ab protein to non-target Lepidoptera, the great egg fly, *Hypolimnas bolina philippensis* Butler (Nyphalidae : Lepidoptera)

Bonifacio Fallorin Cayabyab[1], Edwin P. Alcantara[2], Augusto C. Sumalde[3], Wilma R. Cuaterno[4], Blair Siegfried[5], Josemari M. Belen[6], Ma. Charisma Malenab[7], Karen Ardez[8]

[1]University of the Philippines Los Banos, Philippines, [2]University of the Philippines, Philippines, [3]University of the Philippines Los Banos, Philippines, [4]Bureau of Plant Industry, Philippines, [5]University of Nebraska, U.S.A., [6]University of the Philippines Los Banos, Philippines, [7]University of the Philippines Los Banos, Philippines, [8]University of the Philippines Los Banos, Philippines

Bioassay using the maximum hazard dose (i.e. approximately 10x the maximum Cry1Ab protein concentration in Bt corn) was done by feeding three-day old larvae of the Great Egg Fly butterfly, Hypolimnas bolina philippensis Butler with the natural diet of Ipomoea triloba L. treated with Cry1Ab protein. Leaf discs (2 cm diameter) were soaked in Cry1Ab solution and air dried. One larva was placed inside the plastic cup containing the Cry1Ab-treated leaf disc. The larvae were transferred on leaves without Cry1Ab after 24 hours. For control assay, the leaf was soaked in carbonate buffer. Fifty larvae were used per treatment with a total of nine treatments for each group. Larval mortality and weight were recorded after seven days. T-test was used to analyze the data. Another test on intact leaves of Ipomoea batatas (L.) was prepared. The larvae were placed in air dried leaves soaked in Cry1Ab protein. The treated leaf with twenty five larvae was put inside a black cylindrical board cage to protect the Cry1Ab protein from the degrading effect of light. The intact leaf was used to prevent secondary metabolites effect on the larvae. The same number of larvae and treatments were utilized. The mean mortality (0.632) and mean weight (-0.404) differences on leaf disc method of the treated and control leaves were not significant. Conversely, the mean mortality (-0.0191) and mean weight (-0.957) differences on intact leaves of the two groups were not significant. The findings indicate that the Cry1Ab protein was not toxic to H. bolina.

Canopy-dwelling non-target arthropods present in open pollinated Bt and non-Bt eggplant varieties were monitored in three multi-location trial sites during two cropping seasons in 2010-2011. Visual count of arthropods was done at weekly interval for fourteen weeks. Redundancy analysis (RDA) of abundance data and Principal Response Curve (PRC) analysis of repeated measures to test and display treatment effects that change across time were done using CANOCO for Windows v4.5. Significance was tested using the unrestricted Monte-Carlo method (499 permutations under reduced model). Biplot diagrams of the ordination results from redundancy analysis of abundance data from each site over two seasons were generated using CanoDraw for Windows v4.13. RDA analysis showed that leafhopper, Amrasca biguttula (Ishida)and whitefly, Bemisia tabaci (Gennadius) were the highly dominant species while only two species, lepidopteran leafminer, Phycita clientella Zeller and semilooper, Chrysodeixis eriosoma, (Doubleday) were strongly associated with non-Bt eggplant. However, no significant differences in arthropod communities between Bt and nonBt eggplant varieties across sites over two seasons were detected by PRC. Variance explained by crop type range from 4.2 to 8.5% except at 26.0% in one season for UPLB site while variance explained by sampling period range from 23.4-56.3%.

Effects of GM crops on nontarget organisms: Field studies in India

Mukesh Kumar Dhillon[1], Hari C. Sharma[2]

[1]Indian Agricultural Research Institute (IARI), India, [2]International Crops Research Institute for the Semi-Arid Tropics (ICRISAT), Patancheru, India

Deployment of Bt-transgenic cotton has led to significant reduction in pesticide usage and health hazard, enhanced environmental quality, increased crop production, and improved the efficacy of other pest management tactics. However, the concerns raised regarding effects of large-scale cultivation of Bt-cotton on the nontarget organisms, arthropod biodiversity, development of resistance, and pest resurgence are genuine. Monitoring of arthropods in farmers fields in India indicated that the populations of major nontarget sucking insect pests viz., Amrasca biguttula biguttula, Bemisia tabaci, Aphis gossypii, Oxycarenus laetus, Dysdercus koenigii, and Nezara viridula; and the generalist predators viz., Cheilomenes sexmaculatus, Chrysopa spp., and spiders did not differ significantly between Bt and non-Bt cottons. Species richness and diversity index of the plant inhabiting and soil dwelling arthropods were similar in Bt and non-Bt cottons. However, the reduction in insecticide sprays, especially during flowering and boll formation phases, has resulted in resurgence of some minor pests such as mealy bugs, Spodoptera litura, thrips, aphids, leafhoppers, white fly, and green stinkbug in cotton ecosystem. As a result of reduced insecticide use in Bt-cotton, beekeepers are keeping their bee hives (Apis mellifera) in Bt-cotton in northern India, and have not reported any negative effect of Bt-cotton on the bee colonies. In general, there are no adverse effects of Bt-cotton on the arthropod diversity, nontarget insect pests and natural enemies in the cotton ecosystem. However, regular monitoring of arthropod diversity and surveillance of important insect pests in the Bt-cotton ecosystem is necessary for sustainable deployment of transgenics for crop production.

Effects of Cry1Ac Rice on *Propylea japonica* (Coleoptera: Coccinellidae), *Pirata subpiraticus* (Araneae: Lycosidae) and *Pachygnatha clercki* (Araneae: Tetragnathidae).

Sue Yeon Lee[1], Seung Tae Kim[2], Jong Kook Jung[3], Joon-Ho Lee[4]

[1]Seoul National University, Republic of Korea, [2]Seoul National University, Republic of Korea, [3]Seoul National University, Republic of Korea, [4]Seoul National University, Republic of Korea

The study was conducted to assess the potential adverse effects of a Bt-rice line (japonica rice cultivar Nakdong) expressing a synthetic cry1Ac1 gene, C7-1-9-1-B, which was highly active against all larval stages of Cnaphalocrocis medinalis (Guenee) (Lepidoptera: Pyralidae), on two spiders, Pirata subpiraticus (Bosenberg et Strand) and Pachygnatha clercki Sundevall, and a pollen-feeding predator, Propylea japonica (Thunberg). In the laboratory, P. subpiraticus and P. clercki were supplied with Bt and non-Bt (isoline) rice-fed brown plant hopper Nilaparvata lugens (Stal) and P. japonica was provided with one of three diets: Bt rice pollen with aphid Aphis gossypii Glover, non-Bt rice pollen with aphids, and aphids only. For P. subpiraticus and P. clercki, no negative effects were found on its survival, development, fecundity and adult physical characteristics. For P. japonica, the development time of larvae in the aphid only treatment was significantly shorter than in the two treatments where aphids were provided together with Bt or non-Bt rice pollen, but the survival, development and adult weight were not significantly different between Bt and non-Bt rice pollen with aphids. In a 2-yr field trial, populations of the three predator species were surveyed with a sweep net and suction device throughout the rice growing season in 2007 and 2008. The data show that Bt rice did not significantly affect the population density of P. subpiraticus, P. clercki and P. japonica. The results indicated that Bt rice expressing Cry1Ac had no significant adverse effects on the fitness and the population density of three important predators.

Assessing the impact of GE plants on natural enemies ? testing practices with *Coleomegilla maculate*

Yunhe Li[1], Jorg Romeis[2], Anthony M. Shelton[3], Yufa Peng[4]

[1]State Key Laboratory of Plant Disease and Insect Pests. Institute of Plant Protection, CAAS, China, [2]Agroscope Reckenholz-Tanikon Research Station ARTSciences, Switzerland, [3]Cornell University/NYSAES, U.S.A., [4]State Key Laboratory of Plant Disease and Insect Pests. Institute of Plant Protection, CAAS, China

To evaluate the potential effects of Cry2Ab- and Cry1Ac-expressing cotton on a ladybird predator Coleomegilla maculata (DeGeer), a tritrophic bioassay was conduced using Bt-susceptible and -resistant larvae of Trichoplusia ni as prey. The survival, development time, adult weight and fecundity were not different when C. maculata were fed with resistant T. ni larvae reared on either Bt or control cotton. To ensure that C. maculata were not sensitive to the tested Cry toxins independent from the plant background and to add certainty to the hazard assessment, a tier-1 bioassay was developed where the beetle larvae were fed artificial diet incorporated with Cry2Ab, Cry1Ac or both at > 10 times higher concentrations than in cotton tissue. Artificial diet containing E-64 was included as a positive control. No differences were detected in any life-table parameters between Cry protein-containing diet treatments and the control diet. In contrast, larvae of C. maculata fed the E-64 could not develop to the pupal stage and the 7-d larval weight was significantly negatively affected. In both bioassays, the stability and bioactivity of Cry proteins in the food sources were confirmed by ELISA and sensitive-insect bioassays. Our results show that C. maculata is not affected by Bt cotton and is not sensitive to Cry2Ab and Cry1Ac at concentrations exceeding the levels in Bt cotton, thus demonstrating that Bt cotton will pose a negligible risk to C. maculata. More importantly, this study demonstrates a comprehensive system for assessing the risk of genetically modified plants on non-target organisms.

Pesticides, GM Crops, Resistance and Toxicology

Assessing the impact of bruchid-resistant transgenic legumes on parasitoids

Joerg Romeis[1], Christoph Luethi[2], Fernando Alvarez-Alfageme[3]

[1]Agroscope Art, Switzerland, [2]Agroscope Art, Switzerland, [3]Agroscope Art, Switzerland

Bruchid beetles (Coleoptera: Chrysomelidae) are a major threat to stored cowpeas. Genetically engineered plants expressing insecticidal proteins might be a powerful tool to contribute to the efficient control of this pest complex. The gene coding for the α-amylase inhibitor-1 (αAI-1) from the common bean has successfully been introduced into a range of legumes to protect their seeds against bruchid attack. Whereas αAI-1-transgenic legumes appear to be highly resistant against some bruchid pests, such as Callosobruchus spp., other species are not affected by this insecticidal protein. Consequently, αAI-1-transgenic legumes need to be combined with other methods to provide a better control of the bruchid pest complex. This includes the regulation conferred by natural enemies such as hymenopteran parasitoids. The combination of αAI-1-transgenic legumes with biological control requires that the transgenic trait does not adversely affect the parasitoids. We present a conceptual model and an analysis plan to assess the risk of αAI-1-transgenic legumes to bruchid parasitoids and provide results on the impact of the insecticidal protein on this important group of non-target arthropods.

Developing a famework for assessing the risks associated with RNAi crops on non-target organisms

Xuguo Zhou[1], Blair Siegfried[2]
[1]*University of Kentucky, U.S.A.*, [2]*University of Nebraska, U.S.A.*

Recent discoveries of RNA interference (RNAi) and related silencing pathways have the potential to revolutionize modern agriculture. Besides technical challenges, the lack of a formalized/standardized ecological risk assessment (ERA) procedure is the biggest obstacle to integrate RNAi crops into the IPM rotation. An essential component of the ERA of RNAi plants involves in vivo RNAi toxicity testing under a defined worst-case scenario of exposure. The studies are designed to answer questions directly pertaining to the risk of in planta RNAi to non-target arthropods that are at greatest risk of exposure because of a shared environment and common molecular targets. In this research, we focus on the western corn rootworm (WCR), Diabrotica virgifera virgifera LeConte, one of the most devastating corn pest species in North America and which in planta expression of WCR dsRNAs has been demonstrated to protect corn plants from larval feeding. This report describes the very first step of a tiered approach, which is to measure specific risk endpoints under the worst-case scenario. This early-tier test will provide information on whether the potential hazards of RNA transgenes can be transferred to NTOs representing different habitats and diverse ecological functions. We believe this risk evaluation framework will provide an important model for future ERA of RNAi-mediated pest management technologies.

Pesticides, GM Crops, Resistance and Toxicology

A strategy on countermeasure against further development of pyrethroid resistance of vector mosquitoes: Minimizing the use of pyrethroids by synergistic actions of formamidines and by introducing new

Fumio Matsumura
UC-Davis, U.S.A.

The current strategy for control of vector mosquitoes of human diseases relies heavily on the use of pyrethroids, inviting increasing resistance problems. Here we tested the possibility of using formamidines, amitraz and chlordimeform, as synergists to increase the effectiveness of pyrethroids and neonicotinoids for the purpose of controlling the 4th instar larvae of Aedes aegypti, a vector for dengue disease. Amitraz was found to show consistently more potent synergistic effects than chlordimeform. Against pyrethroids the synergistic larvicidal effects of amitraz was most apparent when larvae were co-treated with deltamethrin or fenvalerate type pyrethroids, but not with permethrin or fenitrothion. Against neonicotinoids, amitraz showed significant synergizing effects, particularly when they were co-treated with the newer type of neonicotinoids such as dinotefuran and thiamethoxam. To gain mechanistic insights we tested our hypothesis that formamidines cause hyper-excitation in mosquitoes through their agonistic action on the octopamine receptor (OR). We indeed found that amitraz consistently elevated the mRNA expressions of octopamine receptor (OR) and trehalase, which were most prominent in the presence of deltamethrin or dinotefuran. Furthermore, significant increases in free glucose levels were found when the larvae were treated with amitraz, which was greatly exacerbated when they were co-treated with deltamethrin, fenvalerate, dinotefuran or thiamethoxam, but not with permethrin, or fenitrothion. These results support our conclusion that the insecticides synergized by formamidines are the ones which cause neuro-excitation which is greatly exacerbated

Integrated measures for managing resistance for major pests in Malaysian crops

Sivapragasam Annamalai[1], Loke Wai Hong[2]
[1]CABI, Malaysia, [2]CABI, Malaysia

The first official indication of insect resistance in Malaysia to insecticides was for the diamondback moth, Plutella xylostella, a major and cosmopolitant crucifer insect pest. Insecticide resistance for this pest was confirmed and quantified in 1978 and gradually it became an icon for resistant - incidentally to all major groups of insecticides, including the microbial Bacillus thuringiensis. Smith's disaster phase was averted by the timely intervention with an ecologically-based integrated pest management approach in the early 80s and 90s. However, recent escalations of this pest and that of another on rice, viz.,the brown planthopper, Nilaparvata lugens suggested maladies in the system. Recent farm surveys on pesticide use in both the crucifer and rice systems indicated the extensive array of pesticides used against the pests and the trying situations faced by farmers. Many cheap and illegal pestcides are also flooding the market. Malaysia's strategy towards sustainability is now under challenge from the the PULL effect of pesticides compounded by weak enforcement and the legislative PUSH towards non chemical approaches and proper stewardship programs for pesticides. The author shares experiences on the strategies used in mitigating or countering resistance and the options and challenges faced in the context of the current socio-economic-environmental scenario.

Mechanisms of negatively correlated cross-resistance between malathion and fenvalerate in the brown plant hopper, *Nilaparvata lugens* Stal

Hayato Teshima[1], Tetsuo Saito[2], Tadashi Miyata[3]
[1]Nagoya University, Japan, [2]Nagoya University, Japan, [3]Nagoya University, Japan

Hayato Teshima1,2, Tetsuo Saito1 and Tadashi Miyata1,3 1) Graduate School of Bioagricultural Sciences, Nagoya University, Chikusa, Nagoya University, Chikusa, Nagoya, 464-8601 Japan 2) Present address: Health & Crop Sciences Research Laboratories, Sumitomo Chemical Co. Ltd., Takatsukasa, Takarazuka, Hyogo Prefecture, 665-8555 Japan 3) International Technical Cooperation Center, Rural Development Administration, Republic of Korea, Suwon, 441-707 Republic of Korea Successive selection with malathion in the brown plant hopper, Nilaparvata lugens Stal, resulted in the development of resistance to malathion but significantly susceptible to fenvalerate. On the other hand, successive selection with fenvalerate resulted in the development of resistance to fenvalerate but susceptible to malathion. Resistance to malathion might be caused by reduced cuticular penetration and enhanced degradation of malathion, and it was considered that higher susceptibility to malathion in fenvalerate selected strain might be caused by lower degradation activity of malathion by selection with fenvalerate. Cuticular penetration, in vivo metabolism and in vitro binding of fenvalerate were investigated. There were no differences in those mechanisms between malathion resistant and fenvalerate resistant strains. Mechanisms of decreasing of resistance to malathion with successive selection with fenvalerate remain subjects for future research.

An ace-1 expression system for monitoring insect acetylcholinesterase activity: With a special reference to carbofuran resistance in rice stem borer, *Chilo suppressalis* Walker

Cheng Chang[1], Xin-Yi Huang[2], Shu-Mei Dai[3]

[1]National Chung-Hsing University, Taiwan, [2]National Chung-Hsing University, Taiwan, [3]National Chung-Hsing University, Taiwan

Rice stem borer, Chilo suppressalis Walker, is one of the most important rice insect pests in Taiwan. Under heavy insecticide applications, more than 1000-fold resistance to carbofuran has been detected in certain field strains of this stem borer. Modified acetylcholinesterases (AChE) with A314S and H668P amino acid substitutions and increased Km and Vmax have been suggested to be associated with this resistance. The aim of this study is to verify the effect of these amino acid substitutions by expressing C. suppressalis AChE in Spodoptera frugiperda (Sf9) cells with the Bac to Bac Baculovirus Expression System. Full-length cDNA of ace1 obtained by RT-PCR was inserted into Bam HI/ Hind III sites of pFastBacTM 1 vector, which was then transformed into DH10BacTM Escherichia coli. The recombinant bacmids with ace-1 were isolated from E. coli and purified for the transfection of Sf9 cells. The recombinant viruses were harvested 96 hours post-transfection and collected as P1 viral stock. For further amplification, two more runs of transfection were carried out. Lysate of P3-infected Sf9 cells exhibited an AChE activity up to 32 ?OD min-1 mg protein-1 with 640 μM acetylthiocholine iodide. This result indicates that Bac to Bac Baculovirus Expression System is suitable and efficient for ace-1 expression. Our study provides a simple method to examine the linkage between the activities/amino acid substitutions of modified AChE and insecticide resistance development in insects.

Resistance to mating disruption, a pheromone-based pest management tool, in the smaller tea tortrix, *Adoxophyes honmai* Yasuda

Jun Tabata
National Institute for Agro-Environmental Sciences, Japan

Pest management using a copy of pheromone to interfere with sexual communication, termed mating disruption, is a possible substitution of insecticides. To date, many moths have been controlled with applications of formulated pheromones as mating disruptants. Repeated treatment with a disruptant, however, could theoretically impose strong selection on the targets, leading to evolutionary change of the pheromone-mediated communication and thereby potentially reducing the efficiency of this approach, as is the case with other insecticides. Indeed, the first example of resistance to mating disruption was documented in the smaller tea tortrix, Adoxophyes honmai, in Japan. To avoid other such cases, we challenged to elucidate why the disruptant was inefficacious. First, we imposed further selection by rearing the resistant colony with the disruptant in the laboratory. The active ingredient in the disruptant was (Z)-11-tetradecenyl acetate (Z11-14:Ac), which is one component of the sex pheromone of A. honmai. After more than 70 generations of selection, a strain with quite strong resistance was established, males of which could find their mates even in the presence of 1 mg/liter of Z11-14:Ac. We then investigated pheromone perception and production of this stain and uncovered that male response to the pheromone blend was markedly extended after selection; the resistant strain males could locate a synthetic pheromone source even when it lacked Z11-14:Ac that is normally indispensable for attracting A. honmai males. Males with the ability to lock on to an off-ratio pheromone blend may be more likely to overcome some of the disruptive effects of pheromone applications.

The ultimate strategy on countermeasure for insect resistance to insecticide

Tetsuo Saito
Nagoya University, Japan

Since 1913 San Jose scale developed resistance to lime sulfur, many researches have been conducted but continue this problem. The origin of resistance is biological adaptation. Dvelpoment resistance has three phases, slow, hasty and stable. The ultimate strategy on countermeasure for insect resistance is insecticides rotation with no cross resistance insecticides with continual field monitoring. At present novel excellent insecticides developed. I hope those insecticides must carry out with judicious application.

Global registration considerations for in planta RNA-mediated control of insect pests

Christina Lawrence
Monsanto Company, U.S.A.

RNA based biotechnology-derived crops have been commercially available and safely consumed for over a decade. Global approvals for products such as virus resistant papaya, potato, bean, and squash, high oleic soybean, FLAVR SAVR tomatoes, and plum trees resistant to plum pox virus have all concluded that these products are safe for food and feed purposes using the current safety assessment paradigm for other biotechnology-derived crops. The RNAi pathway is a conserved, ubiquitous mechanism found in all multicellular organisms investigated thus far. Foods and feeds contain diverse populations of endogenous small RNAs (sRNAs) originating from plants and animals and are a normal part of human and animal diets. Many of these small RNAs are identical to vital mammalian genes and safely consumed. The next generation of RNA based products will utilize dsRNA to elicit a gene suppression response in pest species when produced in planta. The existing GM crop safety assessment paradigm is appropriate for evaluating potential unintended effects or hazards for RNA-mediated insect protected crops and additional studies are determined on a case by case basis to address product specific issues.

RNAi products platform for invertebrates' health and targeted pest control

Eyal Ben-Chanoch[1], Gal Yarden[2]

[1]Beeologics Inc, U.S.A., [2]Beeologics Inc, U.S.A.

Ribonucleic Acid interference (RNAi) applications for invertebrates are on the scientific agenda since RNAi was initially introduced. The work done on C. elegans not only was awarded with the Nobel Prize in 2006, but also triggered many initiatives that focused on how the RNAi mechanism can be used for pest management. RNAi based products are been developed by Beeologics to control honeybee viruses and parasites. The first and most advanced product to be introduced is Remebee® ? an anti-viral agent fed to the bees protecting them from acute infection caused by the Israeli Acute Paralysis Virus (IAPV). This virus has associated with honeybee mortality and identified as one of the potential participating factors of Colony Collapse Disorder (CCD). The technology platform built in the creation of Remebee covers many of the aspects of new product introduction and now supporting the R&D of several complementary RNAi products; for the honeybees as well as a variety of application for targeted pest control.

Developing species-specific RNAi technologies to control insect persts

Steve Whyard[1], Aditi Singh[2], Alison Partridge[3], Andrew Turko[4]
[1]University of Manitoba, Canada, [2]University of Manitoba, Canada, [3]University of Manitoba, Canada, [4]University of Manitoba, Canada

A serious problem for many insecticides is that they can adversely affect or even kill non-target species. In an effort to develop safer, less broad-spectrum pesticides, we have been harnessing the sequence-specificity of RNA interference (RNAi) to develop insecticidal double-stranded RNAs (dsRNAs) that selectively kill pests without impacting others. By targeting either highly divergent, rapidly evolving genes, or the 3' untranslated regions of more conserved genes, we have been able to develop dsRNAs that selectively killed only one species, while leaving closely-related species unaffected. We have been examining several methods of delivery of dsRNAs to insects, and have developed a variety of formulations to feed dsRNAs to a broad range of insects. Despite the apparent lack of dsRNA-specific receptors in dipertans, we have observed potent RNAi and effective pesticidal activity of ingested dsRNA in flies and mosquitoes; some of the endocytotic mechanisms used to facilitate dsRNA uptake in these insects have been identified and their relevance to RNAi in these and other insects will be discussed. We are also working on developing new formulations of dsRNA that may prove more environmentally stable, so that they could be more effective in field applications. While organisms may have thousands of genes that could potentially be targeted by RNAi, choosing the most effective dsRNA and the method of delivery of dsRNA could require some optimization for each pest species, and while this may prove daunting, the benefits of producing safer, more-specific pesticides are worth the effort.

Application of RNAi toward insecticide resistance

Fang Zhu[1], Subba Reddy Palli[2]

[1]*University of Kentucky, U.S.A.*, [2]*University of Kentucky, U.S.A.*

RNA interference (RNAi) is a breakthrough technology for conducting functional genomics studies and also as a potential tool for pest management against insecticide resistance. On one hand RNAi acts as a functional genomics tool to study the molecular basis of physiological functions of target genes associated with insecticide resistance. A brain specific expressed Cytochrome P450, CYP6BQ9 was discovered from the deltamethrin resistant QTC279 strain of Tribolium castaneum. Functional studies using both double-strand RNA (dsRNA)-mediated knockdown in the expression of CYP6BQ9 and transgenic expression of CYP6BQ9 in Drosophila melanogaster showed that CYP6BQ9 responsible for the majority of deltamethrin resistance in the QTC279 strain. On the other hand ingestion bacteria synthesis dsRNA could be used as an application approach to manage insecticide resistant in agricultural important pests. In Leptinotarsa decemlineata, NADPH P450 reductase (CPR) which serves as the partner of all P450s was chose as the target gene for ingestion RNAi. Knockdown the target gene not only significantly decreased the imidacloprid resistant level in adults of imidacloprid resistant strain but also caused dramatically decreased number of eggs laid by adults and the stuck of embryonic development in eggs. These data suggest that ingestion of bacteria synthesis dsRNA of CPR could be used for crop protection against insecticide resistant pests.

Promoted transmission of silencing signals from plant to insect midgut by proteases

YIng-Bo Mao[1], Xue Xue-Yi[2], Xiao-Yuan Tao[3], Dian-Yang Chen[4], Xiao-Ya Chen[5]

[1]Institute of Plant Physiology and Ecology, SIBS, China, [2]Institute of Plant Physiology and Ecology, SIBS, China, [3]Institute of Plant Physiology and Ecology, SIBS, China, [4]Institute of Plant Physiology and Ecology, SIBS, China, [5]Institute of Plant Physiology and Ecology, SIBS, China

Oral ingestion of plant tissues expressing double stranded RNA (dsRNA) resulted in target gene suppression in insect; this offers a potential approach against pest. Previously we reported cotton bollworm (Helicoverpa armigera) fed on transgenic Arabidopsis and tobacco plants expressing dsRNA targeting a bollworm P450 gene, CYP6AE14, exhibited suppressed expression of CYP6AE14 and reduced growth on gossypol-containing diet. We then transferred the dsRNA construct into cotton (Gossypium hirsutum) plants. Growth of the bollworm larvae reared on T2 cotton plants was drastically retarded, and the transgenic plants were less damaged by bollworms than the control. Accordingly, transcripts and protein levels of CYP6AE14 were reduced in the larvae fed on the transgenic plants. The key steps of this method are the production of ingested dsRNAs in plants and the spreading of these silencing molecules into the midgut of insect. Peritrophic matrix (PM), a chitin and glycoprotein layer lining in invertebrate midgut epithelium, presents a barrier preventing dsRNA molecules into midgut. We found that adding proteases into artificial diet elevated midgut permeability and enhanced RNA interference (RNAi) effect in bollworms triggered by plant-expressed dsRNAs. Similar results were observed when transgenic Arabidopsis overproducing plant proteases were used for insect feeding test. We have reported that CYP6AE14 is required for gossypol resistance of bollworm. We show that cotton plants co-expressing dsCYP6AE14 and protease were better protected from bollworm than single transgene lines due to enhanced RNAi effects in the bollworm. Our study demonstrated that RNAi technology for plant protection can be optimized by co-expressing specific proteases.

Effective RNAi targets screening strategy and convenient dsRNA delivery way for Lepidoptera insect pest control

Xuexia Miao[1], Hao Zhang[2], Haichao Li[3], Ruobing Guan[4], Yubing Wang[5]

[1]Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, China, [2]Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, China, [3]Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, China, [4]Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, China, [5]Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, China

To screen RNAi targets from Asian corn borer (Ostrinia furnalalis, ACB), second generation sequencing technology was adopted. Total 14690 stage specific genes were obtained which can be considered as potential targets, and 10 larval stage specific expression genes were selected for RNAi test. When 50 ng/μl dsRNAs of the 10 genes were directly sprayed on the newly hatched larvae which placed on the artificial diet, the mortalities were 73% to 100% at 5 d after treatment. The qRT-PCR analysis verified the correlation between larval mortality and down-regulation of the target gene expression. Topically applied fluorescent dsRNA confirmed that dsRNA did penetrate the body wall and circulate in the body cavity. To investigate whether the dsRNA has species specific or systemic effects in controlling insect pests by RNAi, a storage protein gene (OfSP) was identified from ACB. When the first instar larvae were sprayed with 50ng/μl dsRNA specific to OfSP, levels of the gene transcript decreased significantly. The result of OfSP gene silencing was the larval mortality of 52.54%, the alive larval will be abnormal pupation and failed to develop into adults. When the dsRNA of OfSP gene was sprayed on cotton borer (Helicoverpa armigera) larvae in the same dose, the correct mortality was only 3.6%. These results further confirmed that dsRNA indeed penetrated the insect body wall just by spray on the larvae and cause the systemic RNAi in the insects. It makes the RNAi technology can be easily used in the field of pest insect control.

Controlling corn rootworm with dsRNA: Efficacy, specificity and IRM considerations

William Moar[1], Pamela Bachman[2], Thomas Clark[3], Renata Bolognesi[4], Gerrit Segers[5], Graham Head[6]

[1]Monsanto Company, U.S.A., [2]Monsanto Company, U.S.A., [3]Monsanto Company, U.S.A., [4]Monsanto Company, U.S.A., [5]Monsanto Company, U.S.A., [6]Monsanto Company, U.S.A.

The expression of dsRNA in crop plants, such as maize, to control damaging insect pests such as western corn rootworm (WCR, Diabrotica virgifera virgifera LeConte) represents a new class of insect control traits with a high degree of insect specificity. As with any new plant-expressed insect control trait, the potential for WCR to evolve resistance to dsRNA needs to be considered. This presentation will discuss information regarding pyramiding WCR-active dsRNA with Bt Cry proteins for increased efficacy and decreasing the potential for resistance development while maintaining a relative high degree of specificity in host spectrum

Phytochemical variation: A limiting factor in pesticidal plant applications for small holder farmers in Africa.

Philip C. Stevenson[1], Stephen P. Nyirenda[2], John F. Kamanula[3], Steven R. Belmain[4]

[1]Royal Botanic Gardens, United Kingdom, [2]Lunyangwa Research Station, Departement of Agricultural Research Services., Malawi, [3]Mzuzu University, Mzuzu., Malawi, [4]Natural Resources Institute (University of Greenwich), United Kingdom

Recent surveys of small-holder farmers in Africa indicate that plants are still valued for insect pest control. However, we identified high levels of chemical variability in several pesticidal plants species which was unnoticed by farmers and led to widespread application of ineffective plant materials. We have shown that Tephrosia vogelii, a widely used pesticidal plant that is also grown in fallows to enrich soil, occurs as two distinct chemotypes. Chemotype 1 contained rotenoids, including deguelin and tephrosin which were responsible for the pest control efficacy whereas rotenoids were absent from chemotype 2, which was characterised by prenylated flavanones that are biologically inactive against the insects we tested. Sampling from 13 locations in Malawi where farmers cultivated T. vogelii for insecticidal use indicated that 25% of plants were chemotype 2 and so were unsuitable for this application yet were still being used for pest control. A second species under our study Lippia javanica has several pest control uses including against cattle ticks and the maize weevil Sitophilus zeamais. Activity depends upon perilaldehyde, however, this terpene was not present in all plants and where absent the major component was ipsdienone which was not toxic. Subsequent analysis of herbarium vouchers indicated that chemical variation was associated with different varieties that are possible sub-species and are difficult to distinguish. Meanwhile farmers continue using both sub-species without knowing which is effective. An understanding of the specific chemical variations and knowledge of active components is required to optimise propagation, harvest and use of pesticidal plants.

Variation between individuals in odour responses in *Callosobruchusmaculatus*: Effects of age, sex and morph

Sarah Elizabeth Joan Arnold[1], Philip C. Stevenson[2], Steven R. Belmain[3]

[1]University of Greenwich, United Kingdom, [2]University of Greenwich, United Kingdom, [3]University of Greenwich, United Kingdom

Sex, morph and age may influence responses to behaviour-modifying odours in insects. The cowpea bruchidCallosobruchusmaculatusexists naturally in two adult forms: the active (flight) form for dispersal, and the inactive (flightless), more fecund but shorter-lived form. Given that these morphs show dissimilar biology it is possible that they differ in odour-mediated orientation. However, evaluations of pest control strategies that manipulate chemical ecology, such as the use of pesticidal plants or naturally deterrent crops, do not distinguish between them and rarely consider sex or age. We investigated whether the olfactory behaviour and orientation of C. maculatus towards infested and uninfestedcowpeas and a plant-derived repellent compound, methyl salicylate, differs between morphs or sexes. We found significant differences between the behaviour of male and female beetles and beetles of different ages, as well as interactive effects of sex, morph and age. This study demonstrates that behavioural experiments on insects should control for sex and age, while also considering differences between adult morphs where present in a species. This finding has implications for fundamental entomological research, particularly when exploring the relationships between physiology, behaviour and evolutionary biology, and the application of botanically-derived repellents as crop protection strategies.

Optimisation of acaricidal activity of pesticidal plants *Lippia javanica* (Burm F.) Spreng and Maerua decumbens (Brongn) Dewolf against cattle ticks in Zimbabwe

Brighton Mvumi
University of Zimbabwe, Zimbabwe

The efficacy of 5% w/v Lippia javanica fresh leaves against cattle ticks after hot or cold water extraction; with or without liquid soap (surfactant) was evaluated on-station in comparison to commercial synthetic acaricide and water with surfactant. Mashona cattle, kept in separate paddocks per treatment, were used. Each animal was sprayed (5L) weekly for six weeks between January and February 2011. Prior to spraying and after every other day thereafter, full body tick counts on each animal were recorded. In laboratory bioassays, the effect of a surfactant plus hot or cold water extraction of the leaf powder of the pesticidal plant Maerua edulis applied at 5 to 25% w/v, was compared with solvent extraction. The on-station experiment showed a significant decrease ($p<0.05$) in tick population of different species across treatments. The reduction was higher ($p<0.05$) on cattle treated with L .javanica hot water extracts plus surfactant and the positive control (Tickbuster®) than cold aqueous extracts with surfactant only. In bioassays, there was a general reduction in total tick larval count post incubation in all treatments except the negative control (distilled water). Mortality was significantly higher in hot water plus surfactant treatments than it was in cold water plus surfactant treatments. There was no significant difference in tick larvae mortality between Tickbuster® and methanol-extracted M. decumbens. Use of hot water and liquid soap are low-cost and effective ways of optimizing the acaricidal efficacy of M. edulis and L. javanica and potentially other acaricidal plants under smallholder farming conditions.

Larvicidal and acetylcholinesterase inhibitory activities of *Millettia pinnata* seed constituents toward insecticide-susceptible *Culex pipiens* pallens and *Aedes aegypti* and wild *Aedes albopictus*

Haribalan Perumalsamy[1], Jun-Ran Kim[2], Murugan Kadarkarai[3], Young-Joon Ahn[4]

[1]Seoul National University, Republic of Korea, [2]Seoul National University, Republic of Korea, [3]Bharathiar University, Republic of Korea, [4]Seoul National University, Republic of Korea

An assessment was made of the larvicidal and acetylcholinesterase (AChE) inhibitory activities of the four flavonoids karanjin (1), karanjachromene (2), pongamol (5), and pongarotene (6), and the two carboxylic acids (9Z)-octadecenoic acid (3) and hexadecanoic acid (4) identified in the seeds of Millettia pinnata toward third instar larvae from insecticide-susceptible Culex pipiens pallens and Aedes aegypti and wild Aedes albopictus. Results were compared with those of the conventional larvicide temephos. Karanjin (24 h LC50, 14.61 and 16.13 mg/L) was the most toxic compound, followed by (9Z)-octadecenoic acid, karanjachromene, pongamol, and pongarotene toward C. p. pallens larvae (18.07?25.52 mg/L) and A. aegypti larvae (18.45?25.76 mg/L). Hexadecanoic acid was least toxic (34.50 and 42.96 mg/L). Against wild A. albopictus larvae, (9Z)-octadecenoic acid (18.79 mg/L) was the most toxic compound, followed by karanjin (35.26 mg/mL). The LC50 of karanjachromene, pongamol, and pongarotene was between 52.97?64.97 mg/mL. Hexadecanoic acid (85.61 mg/mL) was least toxic. Overall, all the constituents were less toxic than temephos toward three mosquito species. No correlation was found between contact toxicity and AChE inhibition. Global efforts to reduce the level of highly toxic synthetic larvicides in the aquatic environment justify further study on M. pinnata seed constituents as potential larvicides or lead molecules for the control of mosquito populations.

Insecticidal potential of plants in the Eurasian region - new opportunities for the development of botanical insecticides

Roman Pavela
Crop Research Institute, Czech Republic

Much attention is currently being paid to elimination of environmental and health risks associated with excessive and careless use of synthetic pesticides, not only in EU. Therefore major efforts are currently put into research and development of new environmentally safe preparations based on plant extracts ? the so-called botanical pesticides, which are considered safe for human health and for the environment. In several recent years the research has been also conducted in the Czech Republic with the objective to find new effective substances suitable for the development and production of botanical pesticides. The research focused on plants in the Eurasian region with the objective to identify plants whose extracts contain substances with insecticidal or fungicidal effects. The research involved not only screening of biological activity of plant extracts but, for the commercially usable extracts, also development of preparation formulas and optimization of the production. Some new preparations have been introduced on markets in selected EU countries in a relatively short time. This contribution briefly presents some results of the research dealing with the first stage of the research ? screening of extract effects on insects. It summarizes effectiveness of extracts, obtained from 250 plant species from the Eurasian region, in terms of mortality, antifeedancy and growth inhibition of insects. It also outlines some important problems that accompany the efforts to put results of the research into practice. (Project No. LH11133)

Recent trends in the use of botanical insecticides in North America

Murray B. Isman
University of British Columbia, Canada

The potential of plant extracts and plant natural products for insect management continues to be a subject of considerable research and scientific interest, but the interest from the agrochemical community and consequently the commercial adoption of botanicals lags far behind. Given the logistical and regulatory difficulties faced by companies that have attempted to bring new botanicals to market, it can be argued that more research should be directed toward optimal utilization of existing and recently introduced botanicals rather than the continued search for new plant extracts or plant natural products possessing bioactivity against pest insects demonstrated in laboratory bioassays. Recent use data from California suggest that the growth in use of botanical insecticides has been very modest, in spite of the substantial growth of large-scale organic food production in the state. Botanicals must compete with many more efficacious insecticides, including microbials and reduced-risk synthetic chemicals. In G20 countries, botanical insecticides will be more valued as consumer products than for professional or agricultural applications.

Effect of climate change on the geographical distribution and abundance of insect pests

Jurgen Eberhard Kroschel[1], Henri Tonnang[2], Henry Juarez[3], Marc Sporleder[4]

[1]International Potato Center (CIP), Peru, [2]International Potato Center (CIP), Peru, [3]International Potato Center (CIP), Peru, [4]International Potato Center (CIP), Peru

Climate, especially temperature, has a strong and direct influence on insect development, reproduction and survival and is considered the dominant abiotic factor directly affecting exothermic organisms. It is expected that milder winters will increase the survival rate of pests and will allow a faster population recovery; an extended growing season could benefit multivoltine species to produce a larger number of generations and also increase the risk of invasive pest species; climate change might as well dissociate predator-prey relationships. Understanding and quantifying future shifts in pest range and damage is crucial for any strategy to better manage plant health. We applied temperature-driven pest phenology modeling and risk mapping in a Geographic Information Systems (GIS) environment to assess and understand pest shifts across regions. For simulations, mapping and the quantification of changes, we used the Insect Life Cycle Modeling (ILCYM) software recently developed by the International Potato Center, Lima, Peru. Downscaled future climate scenarios from SRES-A1B projections of the year 2050 were used. Results for several potato pests and related parasitoids will be discussed. As an illustration, the damage potential of the potato tuber moth Phthorimaea operculella, will likely increase in all regions where the pest already prevails today, with an excessive increase in warmer cropping regions of the tropics and subtropics. A possible range expansion into tropical temperate mountainous regions with a moderate increase of its damage potential is also predicted. This information is important to prepare farmers for such change and to develop adaptation strategies to climate change.

Conservation, Biodiversity and Climate Change

Effects of climate change on the population dynamics of arthropods

Keiji Kiritani
National Institute of Agro-Environmental Sciences, Japan

Climate change is one of the driving factors responsible for ecosystem regime shifts, and affects the pattern of population dynamics of arthropods through various ways. For example, global warming can cause a higher over-winter survival, earlier appearance in spring, an increase in the number of generations in a year, lengthening of the reproductive season and so on. Global warming mediated by increases in [CO2] also indirectly affects the development of herbivores through a change in plant quality, such as C/N ratio. The time span required for a regime shift ranges from one year to a decade depending on the life history traits and the distribution range, and the kind and intensity of the driving factors. As long as the regime remains unchanged and the intensity of the driving factor (s) does not overwhelm the regulatory mechanisms in the population, the affected population can recover sooner or later. Even a single-year change in climate, if it allows predators to outbreak, may be strong enough to cause an irreversible regime shift. This suggests that unexpected catastrophes may occur when the impact of climate change disrupts the mechanisms regulating the population. Most insects are susceptible to heat stress between 28 and 32oC, which is lower than what was commonly believed. Climatic change driven by human activities is predicted to lead to an increase of temperature between 1.4°C to 5.8°C by 2100. Thus, global warming could cause a more profound impact on the population dynamics and biodiversity of arthropods than has been previously documented.

Impact of climate change on natural enemies of insect pests

Vincent Foray[1], Patricia Gibert[2], Emmanuel Desouhant[3], Thierry Hance[4]

[1]Earth and Life Institut, Belgium, [2]University Claude Bernard Lyon1, France, [3]University Claude Bernard Lyon1, France, [4]Earth and Life Institut, Belgium

Numerous studies have addressed the effect of global change on physiology, life history traits and population dynamic of species, but few have included species responses in a network context, such as that relating preys and predators. We investigate whether climate changes impact the capacity of natural enemies, mainly parasitoids, to act as regulators of insect pests. Based on a review of the literature and our recent results, we highlight that parasitoids are expected to respond to modifications of the mean temperature and also to the increase of the thermal range, resulting from climate changes. First of all, the performance of adults and the relationship between their size and fitness are deeply affected by temperatures experienced during developmental stages. Secondly, adaptation to a larger thermal variability depends on the phenotypic plasticity and may lead to the selection for generalist strategies. In this case, costs of phenotypic plasticity result in a trade-off between maximum and breath of performance traits, like fecundity, decreasing the efficiency of parasitoids to face to high host densities. Finally, energy allocation between current and future reproduction relies on environmental variability and stochasticity, such that climate changes are expected to decrease the synovigenic index of parasitoids. Dynamic of insect pests and the emergence of new ones have to be analyzed and thermal challenges incurred by parasitoids should be taken into account in biological control programs.

Climate change effects on Insect - host plant - herbivore interactions

Hari C Sharma
International Crops Research Institute for the Semi-Arid Tropics, India

Chemical composition of plants will change in direct response to global warming and climate change, affecting growth and development of insect pests. Moisture stress will lead to either an increase or decrease in insect damage. Water stressed pants, in general, are more susceptible to insect pests. Atmospheric humidity also interferes with insect plant interactions as it influences detection of host plant odors, and thus, may influence host finding and antixenosis mechanism of resistance to insects. Increased levels of CO2 will enhance plant growth, but may also increase the damage caused by some phytophagous insects. Increased CO2 may result in a slight decrease in nitrogen-based defenses (e.g., alkaloids), but increase the carbon-based defenses (e.g., tannins). Environmental factors such as soil moisture, and atmospheric temperature and humidity have a strong influence on expression of Bacillus thuringiensis (Bt) toxin proteins in transgenic plants. Genetically modified cottons with Bt toxin genes have lower nitrogen, and higher carbon-nitrogen ratio, carbon defensive compounds, condensed tannins, and gossypol under elevated CO2, which results in a significant decrease in Bt toxin expression. Decrease in relative humidity and increase in minimum and maximum temperatures increases the efficacy of transgenic cotton against the bollworms, but there is a significant decrease in biological activity once the minimum and maximum temperature are > 22 and > 38 oC, respectively. It is therefore important to understand the effects of climate change on the efficacy of host plant resistance to herbivores for pest management and sustainable crop production.

Towards biodiversity-based ecological IPM: Case in US apple production

David Biddinger[1], Neelendra Joshi[2], Timothy Leslie[3], Edwin Rajotte[4]

[1]Penn State University Fruit Research & Extension Center, U.S.A., [2]Penn State University, U.S.A., [3]Long Island University, U.S.A., [4]Penn State University, U.S.A.

The use of selective insecticides, pheromone mating disruption, and disease-resistant cultivars have the potential to move apple IPM towards sustainability. Conserving biological control agents and native pollinators can reduce the need for pesticides and a reliance on the honey bee for pollination, but rapidly changing arthropod communities in apple orchards and their dependence on features of the surrounding landscape need to be better understood. Regulatory mandates both in the U.S. and in the European Union are greatly restricting or eliminating the use of broad-spectrum insecticides which drastically reduced arthropod biodiversity in fruit orchards for over 50 years. We have documented increases in predator, parastioids and bee biodiversity that set a baseline for the development of a new level of IPM that is not pesticide driven. Ecologically-based IPM is based on understanding the biodiversity that makes up the ecological communities in what should be one of the most stable agroecosystems. We will discuss how climate change and invasive species could upset this stability.

Effect of climate change on bioefficacy of IPM technologies

Mukesh Kumar Dhillon[1], Hari C. Sharma[2]

[1]Indian Agricultural Research Institute (IARI), India, [2]International Crops Research Institute for the Semi-Arid Tropics (ICRISAT), India

Host plant resistance, biopesticides, natural enemies and synthetic chemicals are some of the potential options for pest management, and the relative efficacy of many of these pest control measures is likely to change as a result of climate change. Global warming may result in breakdown of resistance to certain insect pests. Climatic change may also disrupt the balance between insect pests and their natural enemies. The natural enemy ? insect host relationship is influenced by both temperature and relative humidity, which are critical for survival and development of the immature stages of the parasitoids. Postembryonic development of parasitoids is prolonged at cooler temperatures, and the mortality increases at temperature extremes. Conversely, the arthropod predators are directly exposed to the prevailing environmental conditions and experience direct effects of the changing climatic conditions on development and predation potential. Temperature, humidity, elevated atmospheric CO2, and UV radiation also alter the rate of entomopathogenic fungi and nematodes entry into the host insect. Insect viruses are known to be inactivated by high temperatures, sunlight and ultraviolet rays. Sunlight, CO2, and pH exhibit varied influences on the toxicity of synthetic pesticides. Rainfall reduces the insecticide toxicity, however, it varies with the intensity and amount of rain, insecticide formulation and the adjuvants used. Therefore, there is a need to have a concerted look at the likely effects of climate change on the efficacy of different crop protection technologies, and devise appropriate strategies to mitigate the adverse effects of climate change on the bioefficacy of IPM technologies.

Conservation, Biodiversity and Climate Change S901

Impact of climate change on activity and abundance on natural enemies of insect pests

Linda Thomson[1], Ary Hoffmann[2]

[1]*University of Melbourne, Australia,* [2]*University of Melbourne, Australia*

Under climate change, the effectiveness of natural enemies in controlling herbivores will be influenced by changes in distribution of both pests and natural enemies. Natural enemies with effectiveness in controlling pests may decrease if pest distributions shift into regions outside the distribution of their natural enemies, unless a new community of enemies provides some level of control. Pest species with both native and invasive distributions may provide some insight into the likelihood of these scenarios happening. Mealybugs currently considered pests in Australian vineyards include two of Australian origin, long tailed mealybug Pseudococcus longispinus (Targioni Tozzetti) and citrophilus Pseudococcus calceolariae (Maskell), and an invasive, obscure mealybug P. viburni (Signoret); all three also occur in .many countries. At the same time there is concern for two species of invasive mealybugs of importance; vine Planococcus ficus (Signoret) and grape Pseudococcus maritimus (Ehrhorn) mealybugs, both also widely distributed, native to some affected areas and invasive to others. Comparisons of the parasitoid complexes associated with these mealybugs in their ranges of origin and in their invasive ranges provide an opportunity to predict possible outcomes. This talk discusses these possible outcomes and the types of data required to make improved predictions.

Aspects of arthropod ecology : A contribution to sustainable agribusiness in South Africa

Vaughn Richmond Swart[1], Schalk vdM. Louw[2], Mailtland Seaman[3]

[1]University of the Free State Bloemfontein, South Africa, [2]University of the Free State, South Africa, [3]University of the Free State, South Africa

The sustainability of an agribusiness depends on the conservation of its biodiversity. The development of a robust methodology that can be used in an Environmental Management System (EMS) is thus necessary by (i) implementing measures of arthropod and vegetation biodiversity and (ii) incorporating a monetary value to biodiversity, as mechanisms to indicate the degree of disturbance within the agro-ecosystem. Case studies were conducted to pinpoint potential indicators of an ecological nature, with specific reference to the biodiversity of arthropods and vegetation, as part of the methodology. Arthropods were used as an indicator community since they are prevalent, have high species diversity, are easy to sample, are important in ecosystem function, provide early detection of ecological changes and respond to environmental changes faster than vertebrates. The influence of agricultural management practices on the biodiversity is also taken into consideration. Quantitative and qualitative analysis revealed distinct patterns within the biodiversity and is observed at the different locations, relative to the frequency and diversity of vegetation sampled. Thus aspects of ecology (edge-effect, guild structure, biodiversity, etc.) should indicate a relationship between communities, indicating the level of ecosystem integrity. This level of ecological integrity could be taken into consideration when adopting a quality EMS. Possibilities of incorporating a monetary value to biodiversity, that in turn have a bearing on ecosystem services and agribusiness is also addressed. An EMS bio-indicator protocol is important as an aid to reduce the impact of agricultural management practices on the agro-ecosystem and to increase its functional efficiency.

Insect biodiversity: Created dung beetle communities in pastures

Thomas James Ridsdill-Smith[1], John Matthiessen[2], David Cousins[3], Rob Emery[4], Ian Dadour[5]

[1]University of Western Australia,Ecosystem Sciences and CSIRO, Australia, [2]CSIRO, Australia, [3]Department of Agriculture and Food Western Australia, Australia, [4]Department of Agriculture and Food Western Australia, Australia, [5]University of Western Australia, Australia

Species-rich dung beetle communities (Scarabaeinae) have evolved in complex habitats such as tropical forests, and tropical savannahs. These communities are sensitive to human disturbance of the habitats and heavily-modified habitats like improved pastures are typically very species-poor. In the natural forests, woodlands and heath of Australia there is a rich dung beetle fauna, but in nearby improved pastures grazed by cattle the dung beetle community is impoverished. Exotic scarabaeine dung beetles were introduced to pastures in Australia from 1968-1984 to create a community that provides ecosystem services with increased burial of cattle dung throughout the year. The seasonal abundance of the newly created community is described for the agricultural regions of SW Australia which has a cool wet winter growing season and a warm dry summer. The endemic dung beetle species are winter-active. The summer-active introduced species had spread and became abundant by 1993 after 15 years. The summer-active species have two generations a year whereas winter-active species have one generation a year. Winter-active species have spread and become abundant in 2012 after 30 years. This created dung beetle community of 10 species now has a seasonal pattern of beetle biomass similar to that of the natural communities that have evolved in the complex more fragmented woodland and open native pasture habitats found in regions of southern France and Spain with a similar climate.

Using ecological networks to conserve arthropod biodiversity in transformed landscapes

James Stephen Pryke
Stellenbosch University, South Africa

Understanding edge effects between transformed landscapes and conservation areas is critical to conservation planning. Conservation areas in landscape mosaics are often composed of linear corridors, resulting in more edges than would occur naturally. Arthropods are the focal taxa for this study as they are abundant, diverse, and environmentally sensitive at point localities and so represent a wide range of taxa and their responses to anthropogenic change. Plantation forestry has transformed much of South Africa's grassland, with ecological networks (ENs) currently being used to mitigate this biodiversity loss and to maintain ecosystem processes. I compare arthropod biodiversity along transects that ran from within plantation blocks or indigenous forest patches (as a natural reference) into indigenous grassland corridors or into protected areas. Two types of exotic commercial trees and various tree age classes were studied. I found a 32 m edge zone from plantation blocks into grassland corridors. Few significant edge effects from plantation blocks occurred at greater distances than this, suggesting that grassland corridors with a width <64 m are mainly edge. This situation is complex, with different taxonomic groups responding differentially to these edges, although by 32 m from the plantation blocks, arthropod richness and species composition was similar to those of neighbouring protected areas. Indigenous forest supported many additional species, not just within the forest, but also with associated grassland corridors. This means that natural edges are important for maintaining biodiversity, while linkages within transformed habitats need to be wide enough to overcome edge effects.

Arthropod biodiversity in Ethiopia - Religion and science partner for conservation

Margaret Dalzell Lowman
North Carolina State University/Nature Research Center of NC, U.S.A.

Only four percent of Ethiopia's original forests remain, and most of these are small forest fragments surrounding the Coptic churches, many over fifteen hundred years old. As stewards of these last forest tracks, the Ethiopian priests are just beginning to understand the critical ecosystem services provided by these 'church forests' including fresh water springs, pollinators, medicines, honey, biodiversity, and the country's cultural/spiritual heritage. Over the past four years, teams of entomologists have collaborated on arthropod biodiversity surveys of these church forests, prioritizing insect pollinators and canopy biodiversity. In addition to many discoveries of new species and their ecological roles, we have conducted important education outreach to the local children about insects, and worked closely with the church leaders to foster a conservation ethic. The church represents a relatively diverse stakeholder in global forest conservation, but with the strong support of the priests and their parishoners, stone walls have been constructed and restoration of native species is well underway. Continued efforts to classify the arthropod diversity, and education outreach to Ethiopian children, have fostered a new conservation paradigm. The complexities of studying species diversity, in addition to the urgent priorities for habitat conservation and ecosystem services, have led to innovative new models of conservation action plans where economics, ecology, taxonomy, and community sustainability must all become part of the solutions.

Linking forest biodiversity to sustainable livelihood through commercial insects in Africa

Suresh Kumar Raina
International Centere of Insects Physiology and Ecology, Kenya

African forests, which are host to some of the world's richest biodiversity, are rapidly diminishing together with their local flora and fauna. The loss of flora and fauna includes economically and socially important insects, such as honeybees and silkmoths. Grouped under commercial insects, they are a source of insect-based enterprises that provide income to forest-edge communities, thus helping to manage this ecosystem. The realized income is reported to be having a direct impact on households through increased ability to fund children's education and health delivery. The project activities link beekeeping and silk production to Participatory Forest Management (PFM) initiatives in Kenya and several other forests in East and North Africa. The commercial insects enterprises are particularly suitable for use in buffer zones around protected forests. The project also highlights the importance of pollination services in Africa and alternate nutritional sources from agricultural waste. The project has initiated efforts to maintain the health of bees, in view of the recent unexplained disappearance of bee colonies around the world. This seminar will also highlight icipe's and AU-IBAR's recently approved project by the European Commission entitled: African reference laboratory (with satellite stations) for the management of pollinator bee diseases and pests for food security. A central reference laboratory (CRL) will be established at icipe Kenya, as well as four satellite stations (one each in Ethiopia, Cameroon, Burkina Faso and Liberia), to generate new knowledge on bee diseases and pests and their control, for Farmers' Federations (FF) and beekeepers in general.

Butterfly biodiversity in the Australian Monsoon Tropics: A preliminary study

Michael Braby
Biodiversity Conservation Division, Australia

The Australian Monsoon Tropics biome comprises a vast wilderness region across northern Australia with relatively intact savannah landscapes, and includes the Kimberley and Top End as major subregions in the north-west. It is a frontier for biological research and species discovery. The diurnal Lepidoptera (butterflies and day-flying moths) have been selected as one of several surrogate groups to estimate patterns of invertebrate biodiversity within the region. This study seeks to understand the species richness (alpha-diversity), composition and spatial turnover (beta-diversity), spatial distribution and extent of endemism, and threatening processes within the Kimberley?Top End?western Gulf Country. The aim is to use this information to identify sites of conservation significance, and assess the conservation status of each species, with the long-term goal of determining the extent to which invertebrate biodiversity is represented and protected under the current National Reserve System, and to provide recommendations for future reserve design/conservation management. Recent surveys in the region have revealed a number of remarkable taxonomic discoveries that suggest that the level of endemism is higher than previously realised. Attention is briefly drawn to several of these discoveries, one notable example being the presence of a species of Delias which is restricted to tropical mangrove habitats in coastal estuarine areas where it breeds on Euphorbiaceae. The unique habitat association, novel food plant specialisation and narrow geographical range of D. aestiva underscores the biogeographical peculiarities of north-western Australia, especially patterns of historical differentiation between the Top End and Cape York Peninsula within the Australian Monsoon Tropics.

Identifying biome switches by describing the relative role of dispersal vs. environment in structuring ant assemblages

Stefan Hendrik Foord[1], Thinandavha Caswell Munyai[2]

[1]University of Venda, South Africa, [2]University of Venda, South Africa

There has been widespread documentation of woody thickening of mesic savannas across southern Africa. Beta diversity patterns and structure of assemblages in stable environments would be expected to be under environmental niche control, whereas communities in changing assemblages would be dominated by neutral processes. We test this ascertain by determining the relative roles of dispersal and environment in generating beta diversity patterns of ant assemblages on two aspects (xeric and mesic) of the Soutpansberg mountains in South Africa. Ants were sampled with pitfalls traps at 11 altitudinal zones across the mountain. Sixty three percent of the variation in ant assemblage structure on the northern (arid) aspect was the result of environmental sorting processes whereas neutral processes accounted for considerably more of the variation on the southern (mesic) aspect (24 %) than on the northern slope (11%). Ant assemblage composition in sites with historical evidence of thickening is similar to that of the tall forests on the mountain. Ant diversity was also the lowest in sites characterised by thickening. These negative consequences are also predicted for other invertebrate taxa. Global climate change predictions suggest that rainfall in the region will increase by ca. 30%. This could result in increased and widespread thickening with important consequences for the maintenance of savanna species.

Restoring ecological integrity in depauperate agro-ecosystem soils : Disentangling the underlying issues

Schalk van der Merwe Louw
University of the Free State, South Africa

Understanding ecosystem function is pivotal in maximizing outputs in human driven agricultural production systems. Whilst the activities of the above ground components of such systems are well-documented, the below ground biotic community assemblages and their underlying interactions have only relatively recently received more in depth attention. Important in agro-ecosystem function is that, whilst well-established ecological principles apply, several issues deviate from the norm. Central in this context are anthropogenic disturbance and subsequent succession tempos which are often under-emphasized and which need special attention in any agro-ecosystem analysis scenario. Insects, as part of the larger arthropod biodiversity pool in the soil, fulfil a meaningful role in this medium because of their crucial linkages on different levels of the larger trophic structure. In order to provide a reference base for discussion, this paper will refer to the composition and function of various hexapod groups in this regard. Underlying aspects that will receive attention include temporal variability, and landscape scale and heterogeneity, as drivers of change; mismatch between agricultural management and ecological processes; contribution of plant-soil feedback loops in biodiversity enhancement; soil enrichment and the home-field advantage principle; functional shifts and stratification; meta-communities and the rescue-effect principle; site history; and the ecological integrity, agricultural landscape planning and sociology connection. Finally, to address depauperate soil recovery and mitigate soil degradation in agro-ecosystems, recognition of multifunctional agricultural landscapes and integrated adaptation management practices, based on the adaptation models of Holling & Gunderson (2002) and Meinke et al. (2009), are discussed.

Entomology research after the convention on biological diversity

Priyadarsanan Dharma Rajan[1], Prathapan K. Divakaran[2]

[1]Ashoka Trust for Research in Ecology and the Environment, India, [2]Kerala Agricultural University, India

A major snag of the Convention on Biological Diversity (CBD) is a shift in focus from the ecological and scientific value of biodiversity to its commercial value. Articles 3 and 15 of the CBD recognize the sovereign rights of nation states over their biological resources and their authority to determine access to genetic resources through national legislation. Most countries have developed legislations and implementing mechanisms to regulate access to genetic resources within their national boundaries . Unfortunately, the national implementing mechanisms of the CBD decisions, in the hands of the bureaucracy in several countries, have made international collaborations nearly impossible in the fields of systematic, plant protection, management of invasive species and conservation. Most taxa do not have any direct commercial importance and research in basic sciences like taxonomy does not yield any monetary returns but significantly advances the horizons of knowledge. It is rather perplexing to note that the Rules and guidelines framed by the nation states to implement Convention on Biological Diversity , are being irrationally imposed on fundamental research and curtails the scientific freedom. Hence the science community should try to get academic research exempted from the national access and benefit sharing (ABS) regimes under the CBD

Arthropod function and redundancy: A baseline for monitoring environmental change in naturally fragmented habitats across disturbance regimes

Elizabeth Meyer-Milne[1], Serban Proches[2], Eileen Campbell[3]

[1]Nelson Mandela Metropolitan University, South Africa, [2]University of KwaZulu-Natal, South Africa, [3]Nelson Mandela Metropolitan University,

Biodiversity is a crucial but complex concept in conservation ecology. The comprehensive evaluation thereof is challenging and therefore numerous approaches have relied on indicators to interpret selected elements of biodiversity. Arthropods have been found to be the most successful indicators because of their significant role in the overall function of the ecosystem and their sensitivity to environmental change. The indicator approach has however shifted from focussing on single species, abundance and rarity, to incorporating more than one species, different levels of ecosystem functionality and structure, as well as landscape structure. Landscape heterogeneity in particular has been found to play a crucial role in arthropod ecology and dispersal. Mosaic habitats have shown to host significantly high biotic diversities, however most research in this field has focussed on large-scale human induced fragmentation and limited information is available on the functioning of smaller-scale naturally fragmented habitats. This study employed arthropod feeding functional groupings as a tool to indicate ecosystem resilience between naturally fragmented limestone-associated vegetation units in the Eastern Cape province of South Africa. We investigated arthropod relationships across three disturbance regimes and their spatial entities to understand the role of habitat structure in arthropod community structuring and functioning. Locally, this study provides a baseline understanding of the important functions and interactions at play in the Eastern Cape limestone-associated vegetation units for monitoring environment change. Globally, it creates a platform for comparison with limestone associated landscapes, and serves as a model for how to approach biodiversity conservation in small-scale naturally fragmented mosaic units.

Biodiversity soup: Metabarcoding of arthropods for rapid biodiversity assessment and biomonitoring

Douglas Yu[1], Yinqiu Ji[2], Brent Emerson[3]

[1]Kunming Institute of Zoology, China, [2]Kunming Institute of Zoology, China, [3]Kunming Institute of Zoology, China

Traditional biodiversity assessment is costly in time, money and taxonomic expertise. Moreover, data are frequently collected in ways (e.g. visual bird lists) that are unsuitable for auditing by neutral parties, which is necessary for dispute resolution.? We present protocols for the extraction of ecological, taxonomic and phylogenetic information from bulk samples of arthropods. The protocols combine mass trapping of arthropods, mass-PCR amplification of the COI barcode gene, pyrosequencing and bioinformatic analysis. We perform an experimental test and show that we can recover a substantial proportion of the original taxonomic information. We further demonstrate that metabarcoding allows for the precise estimation of pairwise community dissimilarity (beta diversity) and within-community phylogenetic diversity (alpha diversity). Finally, we present applications of metabarcoding to tropical biodiversity censuses. Alpha and beta diversity metrics are the raw materials of ecology and the environmental sciences, facilitating assessment of the state of the environment with a broad and efficient measure of biodiversity.

Conserving pollinators: Can standard restoration mixes restore pollinator diversity?

Alexandra Harmon-Threatt[1], Stephen Hendrix[2]

[1]*Washington University in St.Louis, U.S.A.*, [2]*University of Iowa, U.S.A.*

Conserving native pollinators by restoring native plants is considered critical to preserving their valuable ecosystem service. However, this assumes standard restoration plants are preferred foods for pollinators. This is despite restoration plants being chosen for a number of reasons aside from pollinator diet including plant community structure, seed availability, ease of planting and viability within a restoration. We determined if standard prairie mixes could aid in conserving a significant number of pollinator species. Using extensive records on plant-pollinator interactions in remnant Iowa prairies, we simulated the bee communities that could assemble using standard prairie mixes. We also simulated the bee communities that would assemble if alternate methods were used to choose plants such as plant species abundance in remnant prairies and plant species that had higher bee species associations. Although prairie mixes offer an easy method to begin restoring native plant diversity, species accumulation curves showed that these plant species accumulated fewer bee species at a much slower rate than choosing plants based on bee associations or abundance in remnant prairies. Interestingly, five additions to standard prairie mixes could restore an additional 50% of bee species. Some premier prairie mixes included some of these bee attractive species. This suggests that if money is spent to choose more expensive and more diverse prairie mixes there is a greater chance of success for attracting pollinators. In conclusion, although restoration could improve native bee conservation more targeted efforts need to be made to succeed in conserving pollinators.

Elevational pattern in diversity of butterflies in the Western Himalayas, India

Manish Bhardwaj[1], V. P, Uniyal[2]

[1]Wildlife Institute of India, India, [2]Wildlife Institute of India, India

We studied elevational pattern in butterflies (Lepidoptera: Rhopalocera) species richness and diversity in Tons valley, Western Himalayas. We test a number of hypothesis that were proposed as 'general explanations' for these patterns namely (1) mid-domain effect, (2) overlap between butterfly faunal compositions, (3) water and energy availability and (4) area of elevational bands. Line transects and direct search approaches were used to quantify local species richness and diversity (Fisher's α) at 130 sites during 2009 - 2011. As complete lists as possible have been complied for each 100 m elevational band, starting from an elevation of 900 - 3500 m. For each of the 26 elevational bands, climate and NDVI data have been acquired and plot level microclimatic, vegetation and disturbance parameters were also quantified. A total of 174 butterfly species were recorded and two distinct, lowland and upland assemblages were found. Result shows an overall decreasing pattern in species richness, abundance and diversity with increasing elevation, while evenness was high at higher elevations. Peak species richness and diversity was observed between 1200 - 1500 m. The observed patterns differed significantly from mid-domain null predictions. Area supported an increase in species richness upto mid elevations, while species richness seemed to be controlled largely by climatic variables in high elevation zones. Strongest vegetative predictors of butterfly richness were plant species richness, herb and shrub density. We also evaluated a number of parameters of conservation value and identified sites of most conservation potential in the Himalayan landscape.

Crop pollination services foster rich native bee biodiversity and abundance in western USA

Sujaya Rao[1], William P. Stephen[2]
[1]Oregon State University, U.S.A., [2]Oregon State University, U.S.A.

Conversion of native habitats to crop production is believed to have led to population declines of native bees, especially bumble bees, due to losses in foraging resources which they require over several months for growth and development. However, native bee studies in cropping systems have largely focused on a single crop. Here, our objectives were to determine native bee diversity and abundance in two crops that bloom in sequence. The study was conducted in the agriculture dominated Willamette Valley in western Oregon on the west coast of the United States in commercial fields of spring blooming blueberries and red clover seed crops which bloom in summer. Over 30 native bee species belonging to 10 genera in 5 families were recorded in bee traps. These included six bumble bee species which were also abundant in timed visual counts made in both crops. Bumble bees captured/day increased from 6/trap in blueberries to >30/trap in red clover. Based on visual count data, an average of 1 bumble bee/min foraged on blueberries and 15-30 bees/min on red clover during peak bloom. Thus, in contrast with reports from other regions, a rich fauna of native bees, especially bumble bees, is flourishing in western Oregon. Native bee populations are likely sustained here through the practice of farming bee-pollinated crops that bloom in sequence, and in synchrony with foraging by queens and workers. Based on our studies, we recommend production of multiple crops that bloom in sequence for sustaining native bees in agricultural landscapes.

Insect biodiversity: More than just bugs under climate

Ke Chung Kim
Pennsylvania State University, U.S.A.

Insects are not just 'pest' or 'beneficiary' but six-legged animals, the largest block of global biodiversity, 58-67% of global biodiversity with more than million species so far described that evolved for over 400 million years. Insects are highly resilient and closely associated with humanity as new habitats and hosts are opened up for insects almost everywhere and they are highly resilient for survival. As biodiversity refers to the totality of living organisms at a spatially defined unit, insect biodiversity signifies that insects are not only most species rich and most abundant taxon but also important ecological partners vital to sustaining ecosystem functions. Biodiversity loss has continued without even knowing what they were which would be compounded by the effects of global warming and climate changes. Considering that biodiversity is fundamental to ecosystem function and also primary natural resource for our life-support system the inventory of site-specific biodiversity could provide basic biodiversity database for the target community would provide a baseline information on the species composition of its biodiversity which would help advance sustainable development at the grassroots. This paper will also show how this process is accomplished and how biodiversity and ecological information could be directly applicable to pest management, ecosystem management, and land-use planning along with conservation and application of local biodiversity to local economic and natural resource development. To do so also shows the need for a taxonomic/biodiversity infrastructure for species identification and biodiversity assessment.

Will climate change and biological invasions act synergistically? Response from the ants

Cleo Bertelsmeier[1], Gloria M. Luque[2], Benjamin D. Hoffmann[3], Franck Courchamp[4]

[1]Universite Paris Sud XI, France, [2]Universite Paris Sud XI, France, [3]CSIRO, Australia, [4]Universite Paris Sud XI, France

Ants are among the most devastating invasive species and extremely difficult to control. They can have enormous impacts on native biodiversity and ecosystem functions. In addition, it is generally feared that climate change will favour invasive organisms, especially poikilotherms such as ants, by removing thermal barriers that currently prevent them from invading cooler regions In this study, we compare the potential habitat of 15 of the worst invasive ant species today and following climate change. The species' potential habitat has been estimated using ecological niche models (ENMs) based on 5 different modelling techniques, 3 Global Circulation Models and 2 CO2 emission scenarios, which have been combined in an ensemble forecast yielding a consensual model. Our results are unexpected and question the dogma of the synergism between climate change and invasive species. In brief, there was no unique trend for all of the 15 ant species, with several species increasing in invasive range, several others maintaining a similar range while several species even decreased in invasive range. In addition to this heterogeneity at a global scale, there was a considerable variation across regions for a given species, decreasing in some and increasing in others. Overall, our models indicate that the worst invasive species of today may not be the worst of tomorrow.

Elucidating changes in biodiversity with museum collections and biodiversity informatics

Heather M. Campbell[1], Andrew R. Deans[2]

[1]*North Carolina State University, U.S.A.*, [2]*North Carolina State University, U.S.A.*

Insect collections hold millions of data that are essential to understanding trends in biodiversity: primarily specimens, taxonomic determinations, and collecting events (where, when, and how a specimen was collected and by whom). These data have traditionally been recorded in analog and mostly remain inaccessible to the broader research community. Significant recent initiatives, however, aim to free this knowledge on a large scale, using new tools and data standards. We discuss ongoing initiatives at the North Carolina State University Insect Museum, especially in the context of large-scale digitization initiatives, and make some hopeful predictions about the future of these resources. We also discuss the roles that collections have as nuclei for institutional collaboration and training and as data sources for understanding invasion biology and climate change.

Insect biodiversity science: Toward an integrated discipline for insects

Ke Chung Kim[1], Zhiqi Liu[2]

[1]Pennsylvania State University, U.S.A., [2]China Agricultural University, China

9.1.6. Biodiversity is a unifying concept for the totality of all living organisms included insects and human species. Insects also are the basic resource and ecological partners for sustaining our life support system. As every community is unique in species composition and environmental characteristics, its species composition and biodiversity structure is the essence of biodiversity assessment and the basis for conservation and all other site-based activities which also offers basic educational materials on local biodiversity for K-12 and beyond. Today's knowledge of biodiversity is the culmination of biodiversity research by taxonomists for over 250 years but it is small with barely 1.75 million species documented, less than 20% of 10 million currently extant, of which insects represent over one million species. Taxonomic research must continue to expand our knowledge base on biodiversity, taxonomic training needs enhanced, and taxonomic resource and services readily available for species identification and biodiversity assessment. Biodiversity science integrating taxonomy, community ecology, genomics and application science must take the center-stage for conservation of life; specifically insects that represent the largest block of biodiversity should play a major role in advancing it. In this context insect biodiversity course was developed by integrating all these subdisciplines for a broad audience. This course was first offered in 2008 as Principles of Insect Biodiversity Science at Penn State and then was introduced to the China Agricultural University in Beijing where it was offered in abridged format in 2010. This presentation will share some details of the course.

Abstract: The present work is a comparative analysis of the fossil insect fauna from Hymenaea mexicana, the origin plant of Mexican amber, to the recent insect fauna from Bursera simaruba and Hymenaea courbaril L., the closest related tree to H. Mexicana in Central America. The collection of recent insects was carried out in a Biosphere Reserve within a Mangrove forest located at the pacific coast in the south of Mexico. This region was chosen because it is very similar to the former Mexican amber forest according to the floral composition, climate, and geographic location. The information of the fossil material was gathered from different Mexican amber collections around the world. One special focus of this work lies on the taphonomy of amber. This, to find answers to key questions concerning taphonomic biases and filters of fossilization processes from the former living fauna to the amber faunas of the Miocene Mexican amber forest. Once the taphonomic processes in amber are understood and it is recognized which information is lost and which information is remained in the fossil record, the stability of faunal communities in a Mangrove ecosystem through geological ages can be analyzed and discussed. The results reveal how similar the recent fauna associated with Hymenaea courbaril L and Bursera simaruba is to the fossil fauna of H. mexicana. In addition, the present work is a contribution to the knowledge of the insect biodiversity of a highly diverse Neotropical Region, like southern Mexico.

Taphonomical and ecological implications of fossil and recent Psychodidae (Insecta, Diptera) from Mexico

Frauke Stebner[1], Monica Morayma Solorzano Kraemer[2]

[1]*Steinmann Institute, University of Bonn, Germany,* [2]*Steinmann Institute, University of Bonn, Germany*

The present work is a comparative study of the fossil Psychodid fauna from the Miocene Mexican amber with the extant Psychodidae fauna from Southern Mexico. Today Psychodidae are distributed worldwide and are also well known from the fossil record of several amber deposits. The larvae can be found in various aquatic and terrestrial habitats. Living Psychodidae have been collected in a mangrove region of a biosphere reservat south of Chiapas with vegetation quite similar to the former Mexican amber forest. A comparison of the fossil fauna with the recent fauna provides the opportunity to study insect diversity and the stability of faunal communities over geological time. However, the fossilization in amber is characterized by certain taphonomic processes and the information preserved in amber may be biased.Trichomyia for example is the most common Psychodid genus in Mexican amber. In contrast, this genus is very rare in the collection of recent Psychodidae. This faunal difference might imply that this genus was much more abundant during the Miocene but is rather interpreted as a result of the particular habitats of this genus. Thus, the knowledge of fossilization processes is a necessary condition for interpreting the former fauna and for drawing conclusions on the stability and outlast of ecosystems. The present study directly addresses this problem of bias, loss and conservation of information during the fossilization process in amber.

Pheromone-based management of the red clover casebearer moth, an invasive pest of clover in Canada

Boyd Mori[1], Maya Evenden[2]
[1]*University of Alberta, Canada,* [2]*University of Alberta, Canada*

The red clover casebearer (RCC), Coleophora deauratella, is an invasive seed predator of red clover, Trifolium pratense, in Canada. Larval infestations can cause up to 99.5% seed loss. Insecticide does not significantly reduce damage caused by RCC, and the cost of application is not offset by seed yield. Lack of insecticide control options makes RCC an ideal candidate for pheromone-mediated communication disruption. Sex pheromone-based communication disruption of C. deauratella was examined by application of synthetic sex pheromone in small plot trials. Rope dispensers (Shin Etsu, Japan) and puffers (Suterra, OR, USA) formulated with C. deauratella pheromone consisting of a 10:1 ratio of Z-7-dodecenyl acetate and Z-5-dodecenyl acetate were tested in Alberta. Moth capture was reduced in rope dispenser- and pheromone puffer-treated plots as compared to non-treated control plots. Mechanisms of communication disruption were assessed by comparing the efficacy of pheromone rope dispensers containing the attractive full pheromone blend (10:1 ratio of Z-7-dodecenyl acetate and Z-5-dodecenyl acetate) or major component only (Z-7-dodecenyl acetate) in small plot trials. As well, pheromone rope dispenser density and dose was varied in order to optimize pheromone-mediated communication disruption. The methods used during these field studies can be combined into an integrated pest management program to potentially mitigate the current RCC outbreak.

Pheromone-based monitoring of the weevil pests in the tropics

Gadi V.P. Reddy
University of Guam, U.S.A.

Surveys of major weevil pests (Coleoptera: Curculionidae) of the agricultural crops in the tropics have been conducted and their occurrence has been reported. Ultimately, pheromone-baited traps are developed for population monitoring studies and possibly for the control of the weevil pests. The banana root borer Cosmopolites sordidus is cosmopolitan, and it is one of the main pests occurring in banana plantations throughout the world. The New Guinea Sugarcane Weevil Rhabdocelus obscurus is an introduced pest to Guam and its neighboring islands. Similarly, sweetpotato weevil Cylas formicarius is recognized as the most important pest of sweet potato worldwide and is known to cause considerable damage, with reported losses ranging from 5-100%. All three weevils are economically important pests in the tropics. The cryptic feeding habits of the larvae and the nocturnal activity of the adults make detection and control of infestations difficult. Sex pheromones have been effective in detecting infestations at even low population levels. Consequently, consideration in recent years has focused on synthetic sex pheromones as a potential component in insect control and management of weevil pests. Pheromone-based trapping techniques have been developed by evaluating various trap types and dimensions, color and placement, and heights of the traps in the field on Guam. The results will be discussed.

Chemically-Based Monitoring of the Brown Marmorated Stink Bug, *Halyomorpha halys* (Stal)

Tracy C. Leskey[1], Ashot Khrimian[2], Aijun Zhang[3], Don Weber[4]
[1]USDA-ARS, U.S.A., [2]USDA-ARS, U.S.A., [3]USDA-ARS, U.S.A., [4]USDA-ARS, U.S.A.

The brown marmorated stink bug, Halyomorpha halys (Stal) (Hemiptera: Pentatomidae), is a is native to China, Japan, Korea, and Taiwan, but was accidently introduced into North America in the mid 1990s and has been officially detected in over 35 states in the United States and in Ontario, Canada. This insect has emerged as a pest of unprecedented importance in orchard crops, small fruit, grape, vegetables, row crops, and ornamentals in the mid-Atlantic region of the United States. Danage in apple alone resulted in losses in excess of 37 million dollars based on analysis by the U.S. Apple Association in 2010. Until recently, there was no established method to detect presence, abundance or seasonal activity of brown marmorated stink bug in any cropping system. Here we report on progress to develop a sensitive and reliable pheromone-baited monitoring trap for brown marmorated stink bug to enable growers to make more informed pest management decisions.

Mating disruption of multiple species in horticulture.

Alexandre Ilichev
Department of Primary Industries Victoria, Australia

Pheromone-mediated mating disruption (MD) is an important tool of sustainable, effective and environmentally-friendly Integrated Pest Management (IPM) systems in Horticulture. The successful use of hand-applied MD dispensers for long-term sustainable control of oriental fruit moth (OFM) and codling moth (CM) have been well documented for over 20 years in Australian orchards. At the beginning the general approach was to treat individual orchard blocks and only known host-plant with MD for individual pest species. The ability of OFM and CM to migrate between orchards, quickly invade new host-plants and together damage the same variety stimulated grower's need to cater for both pests in their IPM strategies. Our results of field trials conducted over three consecutive seasons demonstrated that dual-species hand-applied dispensers, designed to disrupt both CM and OFM, were as effective as single-species dispensers applied individually by reducing moth numbers and fruit damage to a similar degree. However, disruption efficacy of some dual-species dispensers was significantly lower near the end of the season for OFM because of depletion of active ingredients. Effective disruption of CM and OFM was also obtained with a multi-species formulation that releases the main pheromone components of both CM and OFM and several leafroller species. Our results provided evidence that simultaneous disruption of several Tortricidae species with a single hand-applied dispenser will be economically advantageous in regions where control of multiple pests is needed in the same variety. Some problems of simultaneous disruption of multiple species in horticultural crops will also be discussed.

Plant volatiles attracting an invasive fruit moth: Basic findings relevant for future monitoring

Silvia Dorn[1], Jaime Pinero[2], Adriana Najar-Rodriguez[3]

[1]ETH Zurich, Switzerland, [2]ETH Zurich, Switzerland, [3]ETH Zurich, Switzerland

In many agro-ecosystems, invasive insect pests threaten the carefully implemented IPM strategies. Monitoring immigrating females is highly desirable. Using the model system composed of the oriental fruit moth Grapholita (=Cydia) molesta and volatiles from its primary host peach, we addressed some basic questions of potential relevance for many cropping systems. The oriental fruit moth is an invasive fruit pest, which is still expanding its distribution range. How does this pest exploit the odor complexity of its host? We showed that female attraction relies on a synergistic interaction of two blend odor constituents, which include even quantitatively minor compounds. Furthermore, how do female moths respond to changing ratios of odor constituents in the blend? Behavioral experiments and neurophysiological studies consistently showed that the ratio specificity of the females is less narrow than previously assumed. This is a promising feature for future field application of volatile blends to assess female incidence and timing of their appearance A relatively robust response of females to changing ratios of volatile constituents might apply to other species as well, as adult females in search of suitable oviposition sites typically have to cope with changing volatile emissions from their host plant in the field. Invited submission: Chemical ecology and crop protection (10-2.)

Use of a plant-volatile moth attractant in resistance management for transgenic cotton.

Peter C. Gregg[1], Alice P. Del Socorro[2], Anthony J. Hawes[3]

[1]University of New England, Australia, [2]University of New England, Australia, [3]AgBiTech Pty Ltd, Australia

We have recently registered a product called Magnet®, for attract-and-kill of adults of Helicoverpa armigera and H. punctigera in Australian cotton. It consists of a mixture of six synthetic (nature-equivalent) plant volatile chemicals, with sucrose as a feeding stimulant. Farmers can add any one of three insecticides. When applied to cotton crops, Magnet® with insecticide is capable of attracting and killing large numbers of moths. It was developed as a component for IPM in conventional (non-Bt) cotton, but this now occupies a very small proportion of Australian cotton acreage, which is dominated by transgenic Bt (Bollgard II ®) cotton. Recent trends in the frequency of resistant alleles for the two Cry toxins in Bollgard II ® suggest that additional tools may be needed for inclusion in future Resistance Management Plans, either to supplement existing measures or to replace onerous requirements such as cultivation to destroy overwintering pupae. In this presentation we will describe experiments aimed at enhancing the productivity of refuges which are used to generate unselected moths by application of Magnet® without insecticide, or (by including insecticide) killing moths emerging from late season cotton, or emerging in spring from fields which grew cotton in the previous summer.

"Attract and reward" as a contribution to pest management

Sofia Orre-Gordon[1], Stephen David Wratten[2], Mattias Jonsson[3]

[1]University of South Australia, Australia, [2]Lincoln University, New Zealand, [3]Swedish University of Agricultural Sciences,

Introduction: Conservation biological control (CBC) can be improved by combining two 'eco-technologies' to enhance the ability of natural enemies to reduce pest populations. In the 'attract and reward' (A&R) approach, synthetic herbivore induced plant volatiles (HIPVs) (attract) are combined with floral resource supplementation (reward). As a result, enemies' ecological fitness are likely to be improved. Methods: A full two-factorial randomized block design was used in Brassicas. Each block included one treatment with a sachet of MeSA, one with flowering buckwheat, one combining the two; the control consisted of the crop alone. The first experiment targeted, three parasitoid, one hoverfly and one lacewing species and Anacharis zealandica at the the fourth trophic level. In the second, peach and cabbage aphids were targeted with their parasitoids and hyper-parasitoids. Results: No synergistic effect of 'attract' and 'reward' was observed in either experiment. Some natural enemy populations increased in response to MeSA, others to buckwheat and some were repelled. MeSA led to had significantly higher aphid parasitism rate. Conclusion Combining MeSA and buckwheat could be beneficial as the two techniques increase the abundance of different natural enemies, as long as any unwanted side effects can be managed.

Root feeders induce volatiles attracting predators

Anne-Marie Cortesero[1], Alan Kergunteuil[2], Celine Josso[3], Sebastien Dugravot[4]

[1]University of Rennes, France, [2]University of Rennes, France, [3]University of Rennes, France, [4]University of Rennes, France

Volatiles resulting from plant ? herbivore interactions play a major role in resource foraging by predators and parasitoids; they can be involved in orientation processes, oviposition or feeding site acceptance or patch quality estimation. In the present study we investigated the influence of dimethyl disulfide (DMDS), a major volatile constituent of Brassica napus roots heavily infested by the cabbage root fly, Delia radicum, on orientation and resource use by its main coleopteran predators. We first carried out laboratory studies where we showed that the staphylinid beetle Aleochara bilineata is strongly attracted by this compound and uses it for microhabitat choice. Attractiveness of this compound was also tested in the field, in a naturally complex odorous environment. Using an original setup, specially designed for ground dwelling beetles, different concentrations of the pure molecule as well as attractiveness of the natural blend emitted by infested roots were tested simultaneously. The main predators of D. radicum (i.e. the two staphylinids A. bilineata and A. bipustulata and carabid beetles of the genus Bembidion) were shown to be significantly attracted by DMDS but responded in different ways both to the natural blend and to the different concentrations tested. The potential resources searched by each species and their specificity for these resources could explain the differences in the responses of the 3 ground-dwelling predators. The possible use of DMDS for enhancing the natural control of D. radicum, a major pest of cabbage crops in northern Europe, will be discussed.

The distribution and host range of SWD from the Eastern Asia with development of diagnostic method using DNA barcode

Deuk-Soo Choi[1], Youngjin Kim[2], Jinyoung Park[3], Tae Gyun Kang[4], Youngho Cho[5], Jong-Chul Jeong[6], Sang-Ho Nam[7], Yoohan Song[8]

[1]Animal, Plant and Fisheries Quarantine and Inspection Agency (QIA), Republic of Korea, [2]Daejeon University, Republic of Korea, [3]Kyungpook National University, Republic of Korea, [4]Gyeongsang National University, Republic of Korea, [5]Daejeon University, Republic of Korea, [6]Korea National Park Service, Republic of Korea, [7]Daejeon University, Republic of Korea, [8]Gyeongsang National University, Republic of Korea

Spotted wing drosophila (SWD) or cherry drosophila, Drosophila suzukii Matsumura, a native of Asia, is a pest of small and stone fruits. This species was first observed in mainland Japan in 1916 and described by Matsumura in 1931. It is a species widely distributed in South Korea and Japan. Although there have been records of causing damage to Korean-type cherries (Prunus tomentosa) within South Korea in 1935, no reports of damages done to any crops have been reported since. Therefore, this species has not been considered as a pest insect, and no studies have been conducted excluding some faunistic survey. In Japan, more studies both taxonomic and ecological, concerning the SWD have been extensively researched. We installed clear plastic bottle traps containing apple cider vinegar (ACV) and wine in 20 sites (mountains, vineyards, table grape packing houses, blueberry orchards, strawberry farms) within Korea, examining the state of SWD population fluctuation from last September. In addition, we conducted a DNA barcode analysis to identify immature stage of SWD. In this symposium, the following subjects will be introduced: first, the state of distribution and host ranges of SWD in Korea and Japan; second, the introduction of research conducted in Korea; third, the identification technique of SWD based on molecular characteristics.

Drosophila suzukii (Diptera: Drosophilidae) in Europe: Geographic distribution, biology and economic impact three years after detection.

Claudio Ioriatti[1], Gianfranco Anfora[2], Giorgio De Ros[3], Alberto Grassi[4]

[1]Fondazione Edmund Mach, Italy, [2]Fondazione Edmund Mach, Italy, [3]Fondazione Edmund Mach, Italy, [4]Fondazione Edmund Mach, Italy

Unlike other Drosophila species, Drosophila suzukii (Matsumura) is economically important as enabling to infest fruits before harvest. In 2009 it was detected for the first time in Italy on raspberry, blueberry and strawberry. The EPPO included D. suzukii in the Pest Alert List; and in 2010 a Pest Risk Analysis was performed as it was considered a threat to all European countries. Extensive monitoring in 2010-2011 in the Italian regions as well as in other European countries confirmed its high dispersal rate and capability to infest a wide range of cultivated and spontaneous hosts. Significant attacks of D. suzukii on some thin skin cultivars of grape was reported in the Northern Italian regions in fall 2011 though not causing economic losses. Three years after the first detection D. suzukii has been reported in 9 countries (Italy, France, Spain, Switzerland, Austria, Slovenia, Croatia, Germany, Belgium). Despite the severe chemical control, important crop losses were found on berry fruits and cherry due to high insect population density and to the patched distribution of the crops. The increasing number of insecticide applications jeopardizes the results obtained with IPM, therefore development of alternative control methods is urgent for an economic safeguard of the concerned fruit industry. Mass trapping and physical crop protection by using anti-insect nets are under experimental evaluation and seems the more promising alternative control strategies accessible in the near future. Improvement of the attraction efficiency of the available lure is the major objective of the research teams dealing with chemical ecology.

Spotted wing *Drosophila*, a new berry and cherry pest in the Western USA

Peter W. Shearer[1], Robert A. Van Steenwyk[2], Denny J. Bruck[3], Elizabeth H. Beers[4], Lynell K. Tanigoshi[5]

[1]Oregon State University, U.S.A., [2]University of California, Berkeley, U.S.A., [3]USDA-ARS, U.S.A., [4]Washington State University, U.S.A., [5]Washington State University, U.S.A.

The spotted wing drosophila, Drosophila suzukii (Diptera: Drosophilidae) was first found in California, USA in 2008 and quickly spread north into Oregon and Washington by 2009. Originally from Asia, D. suzukii is now impacting berry and cherry fruits on both coasts of the USA as well as being found in parts of Europe. This pest is problematic in that it attacks ripening fruit and additional sprays are usually required to control it. Field and laboratory studies indicate that pyrethroids, spinosad, spinetoram and organophosphorus insecticides are the most effective insecticides against this pest. One result of this introduced pest is that integrated pest management (IPM) programs are being negatively impacted because of the need for additional applications of insecticides.

Drosophila suzukii host selection and utilization in eastern United States agroecosystems

Hannah Burrack[1], James Price[2], Rufus Isaacs[3], Dan Horton[4], Cesar Rodriguez-Saona[5], J. Powell Smith[6], Greg Loeb[7]

[1]North Carolina State University, U.S.A., [2]University of Florida, U.S.A., [3]Michigan State University, U.S.A., [4]University of Georgia, U.S.A., [5]Rutgers University, U.S.A., [6]Clemson University, U.S.A., [7]Cornell University, U.S.A.

Drosophila suzukii (spotted wing drosophila, SWD) is a devastating pest of soft skinned fruit that was first detected in the southeastern United States in Fall 2009,following an initial detection in North America in 2008. It has since spread rapidly throughout the eastern US, making it a national pest management issue. Significant SWD damage has occurred in caneberries, blueberries, and grapes throughout the eastern US during the summer of 2011. SWD biology, ecology, and management appears to differ between the eastern and western US and within the eastern US. Low infestation rates and little economic damage have been reported in Florida, while significant infestations and crop losses have occurred elsewhere. Eastern US farmscapes present SWD with a range of crops that have overlapping fruit, and a diversity of native host plants with ripening fruit throughout the summer and fall, providing refuges outside crop fields. Crop infestation rates have been highest in raspberries, and field and laboratory experiments suggest that host species, host variety, and substrate firmness influence both SWD host selection and offspring performance. The implications of host selection and offspring performance are being assessed under field conditions throughout the eastern US and will aid in assessing risk of SWD damage and in making management recommendations.

Seasonal biology of spotted wing drosophila (*Drosophila suzukii*) in California raspberries

Kelly A. Hamby[1], Mark P. Bolda[2], Monise E. Sheehan[3], Frank G. Zalom[4]

[1]University of California, U.S.A., [2]Santa Cruz County Cooperative Extension, U.S.A., [3]Santa Cruz County Cooperative Extension, U.S.A., [4]University of California, Davis, U.S.A.

First reported in California in August 2008, spotted wing drosophila, Drosophila suzukii Matsumura (Diptera: Drosophilidae), is a native of Southeast Asia and a pest of berry and stone fruit crops. Now found in much of North America, D. suzukii is a key pest for raspberry production. Drosophila suzukii pose a particularly strong threat to organic growers, as there are fewer control tactics available. To determine the seasonal population biology of Drosophila suzukii adult flies were monitored weekly via lure-based traps. Field sites were chose to cover the range of raspberry ripening phenology (early, mid, and late ripening), with both an organic and a conventionally managed raspberry site. Apple cider vinegar and yeast + sugar + water lures were used to compare attractiveness, and monthly vacuum samples were taken to ascertain potential sex-ratio bias of the lures. When ripe fruit were available, fruit infestation was measured as average number of larvae per fruit. As might be expected, numbers of adult D. suzukii trapped in each variety begin to increase as the fruit ripened, with fewer flies at the conventional site. Populations build throughout the season and drop off mid-winter. Attractiveness of the lures appears to vary by season. Although the sex ratio of trapped flies does appear to cycle, it does not appear to be an artifact of lure-based trapping. Interestingly, larvae appear in fruit before the first captures of adult flies in the traps. This highlights the need for a more attractive early season trap and knowledge of overwintering behaviors.

Insecticide Resistance Monitoring in *Drosophila suzukii*

Frank G. Zalom[1], Kelly Hamby[2], Denny Bruck[3], Peter Shearer[4], Joanna Chiu[5]

[1]University of California, U.S.A., [2]University of California, Davis, U.S.A., [3]University of California, U.S.A., [4]University of California, Davis, U.S.A., [5]University of California, U.S.A.

Drosophila suzukii (Diptera: Drosophilidae) has become a major pest of cherry and berry crops in North America with current management largely dependent on insecticide applications. Under heavy insecticide selection pressure for last two years and a generation time that may take as few as two weeks under optimal conditions, an ideal situation has been created for the development of resistance. Drosophila suzukii is primarily treated with organophosphate, pyrethroid and spinosyn insecticides in conventional production, but there also exists a particular challenge for organic growers who have fewer and generally less residual options. Fortuitously, D. suzukii is closely related to the intensively studied model organism, Drosophila melanogaster, the organism most frequently used to identify molecular target sites for resistance. Field populations of D. suzukii have been collected from California, Oregon, and Washington for the last two field seasons, then subjected to contact bioassays in a potter tower. A subsample of each of these collections has been preserved for genomic analysis, specifically targeting loci known to confer resistance in D. melanogaster. This has been coupled with a laboratory selection experiment that will attempt to quantify the impact pesticide rotation has on delaying the development of resistance. Preliminary data suggests that fly populations collected from certain California plantations are more tolerant to insecticides. D. suzukii provides a unique opportunity to compare and contrast insecticide resistance in both laboratory and field experiments via contact bioassay and genomic techniques.

Development of monitoring and control techniques against spotted wing Drosophila, *D. suzukii*

Peter Witzgall
SLU, Sweden

Spotted wing Drosophila, D. suzukii (SWD), is a serious invasive pest in Europe. A quick dispersal in Europe together with significant damage in fruit and berries calls for instant action. Three to four years after its introduction to Spain, SWD has become the most important pest insect in fruit growing areas in in Italy, France and Spain. Unlike the ordinary fruit fly, D. melanogaster, SWD oviposits on unripe, but fully grown fruit. Shortly before harvest, spraying with insecticides conflicts with preharvest intervals. In addition, the efficacy of insecticde sprays is not satisfactory. Behaviour-modifying chemicals, pheromones and plant volatile compounds, are widely used for insect monitoring and detection and for population control. The fruit fly D. melanogaster is a model, also for research on the olfactory system. It is straightforward to apply the knowledge of the D. melanogaster olfactory system to its sister species D. suzukii. A first research project on SWD has just been started up, including field studies in Italy and USA. The goal of our research is to develop a monitoring lure and a control technique. A first account of ongoing research will be presented.

Control of spotted wing drosophila (*Drosophila suzukii*) in California cherries

Robert Van Steenwyk
University of California, U.S.A.

The efficacy and residuality of all major insecticide classes for control of spotted wing drosophila will be discussed from field evaluations conducted in California cherry orchards. Timing of chemical control and new control methodology that circumvents many phytotoxicity and residue issues associated with chemical control of spotted wing drosophila will also be reported.

Determining biological parameters of spotted wing drosophila

Vaughn Martin Walton[1], Sam Tochen[2], Jana Lee[3]

[1]Oregon State University, U.S.A., [2]Oregon State University, U.S.A., [3]USDA, U.S.A.

Basic biological parameters of a United States culture of field-collected Spotted Wing Drosophila, Drosophila suzukii, including cold tolerance, temperature-related development, and age-related oviposition and fecundity will be presented. These data were obtained from flies reared on commercially produced fruit and include cherries and blueberries. These data will be compared with data from previous studies conducted on field-collected fly cultures reared on cherries in Japan. We will consider the impacts of humidity on longevity and fecundity of adult female flies. In addition, we will discuss the survival and fecundity of flies of late-dormant survival of overwintering flies provided with nectar and pollen from cherry and blueberry blossoms. The suitability and susceptibility of different commercial fruit at increasing ripeness levels will be presented. Field scouting results from commercial farms will be discussed and directly related to the parameters described above.

CyazypyrTM, a new tool against emerging and old potato insect pests around the globe

Juan Manuel Alvarez[1], I Billy Annan[2], Hector E Portillo[3]
[1]DuPont, U.S.A., [2]DuPont, U.S.A., [3]DuPont, U.S.A.

Cyazypyr™ (DPX-HGW86, cyantraniliprole), is a novel cross-spectrum second generation anthranilic diamide insecticide that was discovered by the DuPont Company, and has proven to be effective at controlling economic insect pests in potato and many other crops. With the over abundance of neonicotinoid insecticides registered in potatoes in the US and other countries, an effective insecticide in a new class is most needed. Cyazypyr™ is the second molecule in the anthranilic diamide class of chemistry to be commercialized, but is the first with significant efficacy on sucking pests. It exhibits a novel mode of action, by selectively activating the ryanodine receptor in insect muscles, resulting in rapid cessation of feeding in affected pest insects. This causes reductions in direct feeding damage and also in the capability of the affected pest insects to vector plant diseases. Field and laboratory testing around the world has shown excellent activity of Cyazypyr™ on most old economically important potato pests and also in the new emerging pests. Cyazypyr™ presents a favorable eco-toxicological and environmental fate profile and also has very low mammalian toxicity. The Environmental Protection Agency in the USA recently granted Cyazypyr™ the Reduced Risk status. Because it conserves many beneficial arthropods, Cyazypyr ™ will be an excellent fit in IPM programs designed for insect pests in potatoes and multiple other crops.

Alternate host induced complexity and vector-virus interactions in potato pathosystem

Rajagopalbabu Srinivasan[1], Juan Manuel Alvarez[2], Felix Cervantes[3]

[1]University of Georgia, U.S.A., [2]Dupont, U.S.A., [3]University of Florida, U.S.A.

Weed hosts serve as reservoirs of aphids and aphid-transmitted viruses in potato (Solanum tuberosum L.) ecosystems worldwide. The Pacific Northwest potato ecosystem is characterized by one such solanaceous weed host, hairy nightshade, Solanum sarrachoides (Sendtner). Experiments indicated that alternate hosts such as S. sarrachoides could significantly improve the fitness of colonizing aphids including the green peach aphid, Myzus persicae (Sulzer) and the potato aphid, Macrosiphum euphorbiae (Thomas). Both aphids performed better on S. sarrachoides than on potato. These effects were further enhanced when S. sarrachoides plants were infected with a Luteovirus, Potato leafroll virus (PLRV). Besides biology, the settling patterns of aphids were also influenced by S. sarrachoides and PLRV infection. Aphids preferred to settle on S. sarrachoides leaflets when compared with potato, and also on PLRV-infected plants than on non-infected plants. In addition, experiments revealed the presence of behavior modifying cues such as visual and olfactory cues that could affect aphid settling. Volatile organic compounds potentially mediating such effects were identified. Further, field studies were conducted to assess the role of these weed hosts on the spatial and temporal spread of PLRV by establishing PLRV inoculum foci. The results revealed that the presence of S. sarrachoides in the vicinity could significantly hasten the primary and secondary spread of PLRV. Observations also indicated that there could be host-specific biotypes that specialize on alternate hosts despite their polyphagous feeding abilities. The implications of the presence of such biotypes on potato viral epidemiology will be discussed.

The potato tuberworm in the USA : An exotic or invasive pest?

Silvia I. Rondon
Oregon State University, United States Minor Outlying Islands

The potato tuberworm (PTW), Phthorimaea operculella (Zeller), is by far one of the most important constraints to potato productivity worldwide. In the USA, PTW has been reported in California, Arizona, New Mexico, Texas, Utah, as far east as in Maryland and Virginia, Oregon, Washington and Idaho. Control of PTW damage is critical because its larvae infest tubers (in the field as well as in storage), rendering tubers unmarketable. There is a zero level of tolerance in processed potatoes. Determining the origin of PTW populations will help us understand how they were introduced and how to prevent further introductions.

Colorado Potato Beetle: Why is it such a pain in the neck?

Andrei Alyokhin
University of Maine, U.S.A.

The Colorado potato beetle is a very important defoliator of potatoes in many potato-growing areas of the world, and it continues to expand its geographic range. Although this insect has received enormous attention from the scientific community, it remains a formidable threat to the potato industry. The beetle has a diverse and flexible life history that is well-suited to a variety of environments. It is also extremely adaptable to adverse conditions, including those created by humans in an attempt to control the pest. The beetles integrate diapause, dispersal, feeding, and reproduction into an ecological 'bet-hedging' strategy, distributing their offspring in both space (within and between host habitats) and time (within and between seasons). As a result, they are a very challenging pest to manage. Unfortunately, there will most likely be no "silver bullet" solution to the problem created by this insect. The only sustainable way to protect potato crops is to integrate multiple control techniques into a scientifically sound management approach. This is not an easy task, but the only alternatives are recurrent crop losses in combination with environmental degradation.

Same diet but different exploitation strategies; an aphid tale.

Philippe Guordanengo[1], Laurence Brunissen[2], Frederic Francis[3], Charles Vincent[4], Anas Cherqui[5]

[1]Univ Amiens / UMR IBSV Sophia Antipolis - France, France, [2]Comite Nord Plants de Pomme de Terre, Beaurains, France, France, [3]University of Liege, France, [4]Agriculture AgriFood Canada, France, [5]University of Amiens, France

Phloemophagous insects have the ability to fine tune plant physiology to exploit their sap diet keeping phloem cells alive and avoiding the clogging of the sieve tubes to maintain sap fluxes. However their interaction with their host plant can in turn alter plant quality. We showed that despite a identical mode of feeding and similar nutritional requirements, potato systemic response to the sympatric aphids Macrosiphum euphorbiae and Myzus persicae varied according to the infesting aphid species. Monitoring aphid feeding behavior using EPG technique revealed that i) heterospecific preinfestation led to reduced plant acceptance only when M. euphorbiae was the preinfesting species ii) in case of conspecific preinfestation both species induced reduced plant acceptance and ii) this alteration of the aphid feeding behavior was due to the expression of a phloem located antixenosis. To start investigating the mode of plant manipulation by these two aphids, we developed a proteomic approach and showed that protein patterns of potato phloem sap strongly varied depending on the species of the infesting aphid. Different proteins, in particular a NBS-LRR one, are specifically induced or repressed in response to one or the other aphid. Taken together, these results suggest that much more than M. euphorbiae, M. persicae needs to deeply manipulate plant physiology to ensure a compatible interaction with the plant. On the one hand the long lasting coevolving between M. euphorbiae and the Solanum species, on the other hand the larger host plant spectrum exploited by M. persicae could explain such variations in potato response.

The potato virus Y tale: Studying the aphid vectors and preventing transmission

Yvan Pelletier[1], Xianzhou Nie[2]
[1]Potato Research Centre, Canada, [2]Potato Research Centre, Canada

Potato virus Y (PVY) (Potyviridae; Potyvirus) is one of the most widely distributed pathogens in the potato crop worldwide, causing significant yield reductions and quality degradations in potatoes. It is transmitted in a non-persistent manner by several species of aphids. New molecular tools are now available to identify PVY vectors in the field. Host selection behaviour on potato is modulating the efficiency with which a given species of aphid is transmitting the virus. Mineral oil is the only effective way to inhibit transmission. The concentration and location in the plant of mineral oil are critical to observe effective protection of the potato crop.

The impacts of soybean aphid, a recent invasive to North America, on seed potato production

Jeffrey Davis[1], Edward Radclifee[2], David Ragsdale[3]

[1]Louisiana State University Agricultural Center, U.S.A., [2]Louisiana State University Agricultural Center, U.S.A., [3]Louisiana State University Agricultural Center, U.S.A.

Prior to the arrival of the soybean aphid, Aphis glycines Matsumura, the primary aphids caught in Midwest potato fields were grain aphids and the turnip aphid, Lipaphis pseudobrassicae (Davis). Soybean aphid now makes up more than 47% of aphids caught in potato fields. Thus, our research focused on soybean aphid and the impact its arrival was having on potato seed production. Soybean aphid is a capable Potato virus Y (PVY) vector (33% vector efficiency), transmitting all PVY strains equally. Soybean aphid is also a vector of Potato leafroll virus (PLRV) (7% vector efficiency) and when in high populations, can significantly influence field spread of PLRV. Soybean aphid does not colonize potato but does land in potato fields with two distinct peaks in the growing season; early June and late August. Electrical penetration graph studies indicate soybean aphid probes just as often and as long as green peach aphid, Myzus persicae (Sulzer). Since few potato seed lots are entirely PVY-free when planted, cultural techniques to limit virus spread such as crop borders and mineral oils are now less effective due to soybean aphid. The failure of potato seed certification programs to end the PVY epidemic and the fact that cultural practices that have been effective in the past are no longer able to control PVY spread, clearly indicates the impact this invasive virus vector has had on North American seed potato production.

The state of commercial augmentative biological control: Plenty of natural enemies, but a frustrating lack of uptake

Johan Coert Vanlenteren
Wageningen University, Netherlands

In commercial augmentative biological control, natural enemies are mass-reared in biofactories for release in large numbers to obtain an immediate control of pests. The history of commercial mass production of natural enemies spans a period of roughly 120 years. It has been a successful, environmentally and economically sound alternative for chemical pest control in crops like fruit orchards, maize, cotton, sugar cane, soybean, vineyards and greenhouses. Currently, augmentative biological control is in a critical phase, even though during the past decades it has moved from a cottage industry to professional production. Many efficient natural enemies have been discovered and more than 230 species are commercially available today. Natural enemy producers developed quality control guidelines, mass production, shipment and release methods as well as adequate guidance for farmers. However, augmentative biological control is applied on a frustratingly small acreage. I will review trends in research and application, causes explaining the limited uptake and ways to increase application of augmentative biological control.Ref: Lenteren, J.C. van, 2012. The state of commercial augmentative biological control: plenty of natural enemies, but a frustrating lack of uptake. BioControl 57: 71-84. DOI: 10.1007/s10526-011-9395-1.

Biological control of *Tuta absoluta* by new species of Heteropteran predators

Vanda Helena Paes Bueno[1], Joop C. Van Lenteren[2]
[1]*Federal University of Lavras, Brazil,* [2]*Wageningen University, Netherlands*

The tomato leafminer Tuta absoluta is native to western South America, but is now an extremely devastating pest in tomato crops in most of South America, Europe and Africa North of the Sahel. This pest can cause yield losses up to 100% and decrease of fruit quality in open field and greenhouse crops. In addition to this pest, in Brazil two other lepidopteran pests - Neoleucinodes elegantalis and Helicoverpa zea - are very important on tomato. For control of the three pests, frequent applications of pesticides of up to 5 times per week are needed, and these resulted in the appearance of resistant populations to a number of active ingredients and the elimination of natural enemies. Biological control may offer a better and safer opportunity for control of these pests. Mirid predatory bugs are currently used with success in Europe to control T. absoluta. In Brazil, three newly found mirid species are now under evaluation. In the evaluation process, two questions emerged: (1) what might be the best type of natural enemy for control of T. absoluta and the other lepidopteran pests: predators or parasitoids, and (2) what characteristics should first be studied to identify an efficient predator of T. absoluta? Recent work on the new Brazilian predators will be presented and the evaluation process will be discussed.

Influence of natural and supplemental lighting on predation and oviposition by predatory mites on western flower thrips

John Les Shipp[1], Laura Hewitt[2], Rose Buitenhuis[3], Cynthia Scott-Dupree[4]

[1]Agriculture and Agri-Food Canada, Canada, [2]University of Guelph, Canada, [3]Vineland Research and Innovation Centre, Canada, [4]University of Guelph, Canada

Lighting conditions in the greenhouse vary substantially with the season. In addition, supplemental lighting is becoming more common in northern temperate greenhouses in order to provide year round production of greenhouse vegetables. Anecdotel evidence suggests that the performance of the predatory mites, Amblyseius swirskii and Neoseiulus cucumeris differs between summer and winter climatic conditions. Both species provide effective biological control of western flower thrips during the summer period, but control of thrips can be much more difficult during the winter season. Earlier studies for N. cucumeris indicate that light intensity or photoperiod did not influence its predation rate, but, perhaps, lighting conditions did impact its oviposition rate. In the past, temperature has been shown to influence the predation rate of N. cucumeris. However, oviposition was not significantly affected. Also, very little information is known about the influence of supplemental lighting on the control efficiency by predatory mites. For supplemental lighting, light emitting diodes (LEDs) and high pressure sodium lamps are the predominate light sources. The current study examines the influence of seasonal natural lighting, LED lighting and temperature on the predation and oviposition rates of N. cucumeris and A. swirskii when offered first instar western flower thrips as the only food source and its impact on these mites as biological control agents.

The effect of photoperiod and light quality on biology of *Macrolophus pygmaeus*, a predator of whiteflies

Anne Ida Nissinen[1], Delia M. Pinto[2], Riitta Irene Vanninen[3]
[1]MTT Agrifood Research Finland, Finland, [2]MTT Agrifood Research Finland, Finland, [3]MTT Agrifood Research Finland, Finland

Fecundity, longevity and egg hatching of the predatory bug Macrolophus pygmaeus was studied in three experiments under artificial lighting in growth chambers to assess if light quality and photoperiod affect its poor establishment in winter-time tomato crops at northern latitudes. In the first experiment, the effect of photoperiod was studied using fluorescent bulbs (FLs) at 16L:8D, 13L:11D, 11L:13D, and 8L:16D at 180 µmol m-2s-1. In the second, the effect of light quality was assessed by producing the 16L:8D photoperiod with FLs, HPSLs and HPSLs supplemented with red LEDs (11 + 5h). In the third, 16L:8D, 11L:13D, 8L:16D photoperiods were produced by HPSLs and 16L:8D with FLs. In all treatments, females (feeding on Ephestia kuehniella eggs on tobacco leaf disks) oviposited and the eggs hatched: no reproductive diapause was induced. Fecundity increased with decreasing photoperiod irrespective of light quality. In FLs, fecundity was significantly lower than in HPSLs alone or in HPSLs + red LEDs in one experiment, whereas no difference was found between FLs and HPSLs in the other experiment. The results suggest that HPSLs do not adversely affect reproductive biology of the bug, and that part of the long photoperiod could be replaced with red LEDs without negatively affecting the bug's biology. The 16-hour photoperiod produced by artificial lighting in year-round tomato production, however, is not optimal for the fecundity of M. pygmaeus. Further research is needed from greenhouse winter conditions where the bugs perceive also the natural light quality and short photoperiod.

Impact of secondary parasitism on *Aphidius colemani* in the banker plant system on aphid control in commercial greenhouses in Japan

Koukichi Nagasaka[1], Naoyuki Takahashi[2], Toshihiro Okabayashi[3]

[1]NARO Agricultural Research Center, Japan, [2]Kochi Agricultural Research Center, Japan, [3]Kochi Prefectural Government, Japan

In order to elucidate the impact of secondary parasitism on a banker plant system, the aphid parasitoids on banker plants were surveyed for four years at commercial greenhouses producing eggplant and sweet pepper in Kochi Prefecture, Japan. A banker plant system using Aphidius colemani was introduced into the greenhouses in November or December for the control of pest aphids from February through May. The mean ratios of secondary parasitoids to the total parasitoids on the alternative host aphid (Rhopalosiphum padi) on banker plants were less than 35% in the early season. In March or April, the mean ratios exceeded 40%, and they reached more than 70% by May or June. Mainly, three species of secondary parasitoids, Alloxysta sp. nr victrix, Dendrocerus laticeps and Syrphophagus sp., occurred through the season. In addition, Asaphes suspensus and Pachynouron aphidis occurred in the later season. In March and April, the higher ratios of secondary parasitism on banker plants had a significant influence on the failures in aphid control during the main harvesting season. On crop plants, higher ratios of secondary parasitism in any season tend to induce failure in aphid control. Though such a negative influence has been suggested theoretically, and has also been supported through some trials of the banker plant system in small greenhouses, no study has heretofore demonstrated the relationship between secondary parasitism and aphid-control results in commercial greenhouses using the banker plant system.

Development of a banker plant system for *Aphidoletes aphidimyza* (Diptera: Cecidomyiidae) to control aphids on sweet pepper from summer to autumn in Japan.

Junichiro Abe
NARO Western Region Agricultural Research Center, Japan

A banker plant system has been used to control pest aphids, mainly on solanaceous crops in greenhouses, from autumn to spring in Japan. The system consists of barley as banker plant, Rhopalosiphum padi (L.) as alternative host, and Aphidius colemani Vierek as a natural enemy. However, use of this banker plant system becomes impractical under high temperature conditions from late spring to early autumn because of the poor growth of barley plants. In addition, the outbreak of hyperparasitoids of A. colemani causes a severe reduction of the control effect of the banker plant system, especially in the hot season. To avoid such problems, a new banker plant system using the aphidophagous gall midge, Aphidoletes aphidimyza (Rondani), is being developed as an alternative method. To establish such a system using A. aphidimyza, the reproduction of four cereal aphid species, Melanaphis sacchari (Zehntner), R. maidis (Fitch), R. padi (L.), and Schizaphis graminum (Rondani), reared on sorghum or barley, was compared under four constant temperatures. The results showed that the reproduction rate of M. sacchari, reared on sorghum, was the highest among all combinations at high temperature. The efficiency of the banker plant system using sorghum seedlings, M. sacchari, and A. aphidimyza in controlling aphids on greenhouse sweet peppers was evaluated in Maizuru City, Kyoto Prefecture. The density, and the frequency of occurrence, of pest aphid on the sweet pepper plants were suppressed more effectively in the greenhouses with the sorghum banker system than in those with barley banker system.

Competitive interactions between aphelinid parasitoids and the implications for population stability and biological control applications

Nian-Wan Yang[1], Fang-Hao Wan[2], Hai-Yun Xu[3], Lu-Lu Ji[4]

[1]Chinese Academy of Agricultural Sciences, China, [2]Chinese Academy of Agricultural Sciences, China, [3]Chinese Academy of Agricultural Sciences, China, [4]Chinese Academy of Agricultural Sciences, China

In classical biological control, introducing single or multiple natural enemy species to reduce the density of an invasive pest to a tolerable level is the longtime debate. Bemisia tabaci (Gennadius) biotype B is the most serious invasive pest in China. To manage this superbug, two promising parasitoid species of whitefly, Eretmocerus hayati (Rose and Zolnerowich) and Encarsia sophia (Girault), were introduced into China in 2008. To better understand the consequence on pest suppression by competitive interactions between natural enemies. First, their ecological suitability, including the temperature, host plant and host instar suitability, as well as the shifting host handling strategy under varying host densities were investigated. Subsequently, the host discrimination ability of parasitoid females on conspecific and heterospecific parasitized hosts, as well as the handling efficacy on such parasitized or healthy hosts was measured. The results suggesting that at low host density, when the accepted host instars range overlapped, this two species may interfer to one another. To reveal whether the interference between this two parasitoids reduce the biological control efficacy, we tested the consepecific and the heterospecific interference competition including hyperparasitizing, multiparasitizing and host-feeding on parasitized hosts. Finally, a field cage release experiment was conducted. The results coincided with the laboratory competition experiment, that two parasitoid species coexisted through a balance between the competitive advantage afforded by interference competition and the primary predator or parasitoid's greater efficiency at attacking the pest, and the control effect of combined release was higher than that of single species release.

Bee vectoring technology for crop protection and recent studies in Korea

Hong-Hyun Park[1], Les Shipp[2], Jeong Jun Kim[3], Peter Kevan[4]

[1]National Academy of Agricultural Science, RDA, Korea, Republic of, [2]Agriculture and Agri-Food Canada, Canada, [3]National Academy of Agricultural Science, RDA, Republic of Korea, [4]University of Guelph, Canada

Bee-vectoring technology uses the capacity of bees that can carry fungal spores, bacteria and viruses as well as pollens, to deliver microbial control agents for crop protection purposes. Microbial control agents for controlling plant diseases and insect pests are delivered to flowers or leaves of plants during the pollination activities of bees. Both successful crop protection and pollination can be achieved through the manipulation of this technology. Since the early 1990s, this technology has been developed and has showed good potential for crop protection. However, the adoption of this technology at farmer's fields is still low. The aim of this study was to enhance the practical application of this technology. Three components are important to the successful application of bee vectoring: microbial control agents, dispenser design, and safety to the vector. Through the screen cage experiments using a Bacillus thuringiensis (Bt) product for the last three years, we could collect detectable densities of Bt from the flowers and leaves of sweet pepper and confirm Spodoptera litura control effect using this technology. We also designed a new dispenser for the bumble bee, Bombus terrestris, to improve their activities and delivery rate of microbials. The effects of several commercial microbial agents (Bt aizawai, Bt kurstaki and Bacillus subtilis) on the safety of bumble bees were tested through the cage trials, and some preliminary observations in greenhouse tomatoes were also done. Our studies have shown that it is critical to review these key components for feasibility before field application for the bee-vectoring technology.

Evaluation of integrated and biological control of a new virus disease, *cucurbit chlorotic yellows virus* (CCYV), transmitted by whiteflies, using a simple mathematical model

Eizi Yano[1], Yutaka Gyoutoku[2]
[1]*Kinki University, Japan,* [2]*Kumamoto Prefectural Agricultural Research Center, Japan*

The cucurbit chlorotic yellows virus (CCYV) is a new virus which was first recognised in Japan in 2007. This virus is transmitted by both type B and Q of Bemisia tabaci and cause serious damage on cucurbits in greenhouses. Bemisia tabaci easily develop resistance to insecticides if farmers only rely on application of chemicals. IPM system has to be developed to suppress this virus disease. A difference equation model has been developed to predict infection of melon plants by CCYV in a greenhouse. The model can predict the number of infected plants and whiteflies every 10 days and calculation using the model is easily performed by Excel 2007. It is assumed that a whitefly adult becomes viruliferous after inoculating infected plants for 10 days and loses its ability of transmitting virus if it does not suck fluids from infected plants for 10 days. The latent period of infected plants until development of the first symptom of the virus disease is assumed to be 20 days. Other parameters of the model are the reproductive rate of whiteflies and the number of plants which one viruliferous whitefly adult can transmit the virus in 10 days. It was predicted from the model that all plants are infected 40 days after the first appearance of the symptom of the virus disease. The effectiveness of biological control, screening, use of resistant varieties for suppressing the disease is evaluated using the model.

Developing IPM for artificially lighted year-round crops: An activity theoretical approach

Riitta Irene Vanninen[1], Marco Pereira-Querol[2], Jenny Forsstrom[3], Yrjo Engestrom[4]
[1]MTT Agrifood Research Finland, Finland, [2]University of Helsinki, Finland, [3]ProAgria, Osterbottens Svenska Producentforbund, Finland, [4]University of Helsinki, Finland

Change Laboratory, a method to help practitioners to develop working practices, is presented here as a tool for supporting collaborative transformation of the innovation process of pest management. The tool was initially used in Finnish Ostrobothnia greenhouse cluster to develop collective management strategies against the greenhouse whitefly in the current conditions and in anticipation of the potential invasion of Bemisia tabaci. We present how the whitefly problem and its ramifications were analysed and modelled in the Change Laboratory process, and introduce the initial solution concept that was developed in collaboration by growers, local advisors and researchers. The basic models of the solution concept are pest monitoring and knowledge sharing between growers as well as learning from each others' pest management actions. Furthermore, spreading of these activities from the initial study site into other villages in the area in the form of a collaborative study and problem solving group that is by the local advisors was an expansion of the initial solution concept. Based on the problem analysis and solution concept the research collective focused itsfirst research efforts on developing economic thresholds and sampling designs to improve and economize monitoring. The process and its results were analyzed in terms of how the participants' agency and learning evolved in the process, how the process deviated from the planned one, and how the object of activity, i.e. the whitefly and its management, of the interacting key activity systems (i.e. greenhouse companies) was shaped in the process.

Integration of biological and chemical control in greenhouses in California: A brief history and future directions

Michael P. Parrella
University of California, United States Minor Outlying Islands

California's floriculture had a value of $1.01 billion in sales, comprising 25.4 percent of the United States total wholesale value. Cut flower production in California is particularly strong, accounting for about 77.3 percent of the total cut flower wholesale value in the country. Grown for its aesthetics, floricultural crops have been heavy users of traditional pesticides, and economic thresholds were virtually non-existent. Today growers recognize that spraying repeatedly does not provide 100% control and leads to resistance problems. Thus more and more growers are turning to the use of 'reduced risk' pesticides and biological control. Greenhouse whiteflies (Trialuerodes vaporarium),two-spotted spider (Tetranychus urticae), Western Flower Thrips (Frankliniella occidentalis), and the serpentine leafminer(Liriomyza trifolii) are still the major pests of many floriculture crops and are the targets for both reduced risk pesticides and biological control. Ongoing research will be reviewed that is focusing on the integration of newer botanical and insect growth regulator insecticides with: Phytoseiulus persimilis/Amblyseius californicus for spider mite control; Encarsia formosa for whitefly control; Hypoaspis sp./A. swirksii for thrips control; and Diglyphus begini for leafminer control. The commercial availability of natural enemies makes this possible at the grower level, although many are questioning the sustainability of these integrated programs due to cost. Overall, these programs have been successfully adopted in California. Pesticide use in greenhouse floriculture has declined from 95,000 to 49,000 pounds active ingredient from 2001 to 2010, respectively; even though acreage devoted to this crop has increased by more than 15% during this time.

Insect life tables: Theory, data analyses, and their applications

Hsin Chi[1], Yu-Bing Joyce Huang[2]

[1]National Chung Hsing University, Taiwan, [2]National Chung Hsing University, Taiwan

Survival, stage differentiation, and reproduction are the critical elements of insect populations and are capable of revealing the population's fitness. Because the traditional female age-specific life table ignores the stage differentiation and male population, its application is limited. The age-stage, two-sex life table can take the variable developmental rates among individuals and both sexes into consideration; it can precisely describe the survival, stage differentiation, and reproduction. When reporting an age-stage, two-sex life table, the following information should be included: 1. The initial size of cohort (N), 2. The number of emerged females (Nf), 3. The age-stage survival rate sxj, 4. The age-specific survival rate (lx) and fecundity (mx). 5. The preadult mortality. Demonstrated by mathematical proof, the jackknife technique should not be used to estimate the variance of population parameters. Age-stage consumption of an insect population is important in determining the economic threshold of pests and the predation capacity of predators. To compare the potential of predators as biological control agent, we propose using the finite predation rate to include the age-stage predation rate, the population structure, and the growth rate of the predator. Computer simulation based on an age-stage, two-sex life table is capable of revealing the change of stage structure and the consumption of the pest population, as well as the interaction between the predator and prey populations. Therefore, it is a useful tool in accessing EIL, timing the release and determining the number of predators required for biological control, etc.

Population-level effects of two acaricides and their mixture on *Tetranychus urticae* (Acari: Tetranychidae)

Aurang Kavousi[1], Zahra Zarei[2], Hassan Rahmani[3], Hadi Mosallanejad[4]

[1]University of Zanjan, Iran, [2]University of Zanjan, Iran, [3]University of Zanjan, Iran, [4]Iranian Research Institute of Plant Protection, Iran

Demographic toxicology based on life table analysis is suggested as the best way to study the effects of toxicants. In this study, the effects of the two acaricides, fenpyroximate , propargite, and their mixture on life history traits and life table parameters of Tetranychus urticae Koch are compared. Female adults were treated with the LC50 concentration. The age-stage, two-sex life table theory was used for data analysis. Life table parameters were calculated using the bootstrap method. Among the tested acaricides, the lowest values of the intrinsic rate of increase (r), finite rate of increase (λ) and net reproductive rate (R0) were seen in treatment with fenpyroximate (0.0913 d-1, 1.0957 d-1 and 2.8875 offspring, respectively) and the highest values belonged to those treated with propargite (0.1174 d-1, 1.1246 d-1 and 4.1861 offspring, respectively). The generation times (T) were 11.4714, 12.1347 and 12.3720 d for mites treated with fenpyroximate, propargite and the mixture, respectively. Treatment with fenpyroximate caused the shortest adult longevity of 2.55 d compared to the 4.19 d of propargite and the 3.96 d of the mixture. Fenpyroximate also led to the lowest mean fecundity of 5.96 offspring compared to propargite (7.15 offspring) and the mixture (8.46 offspring). Population projections revealed the differences in stage structure among treatments.

Performance of dusky-veined walnut aphid, *Panaphis juglandis* (Goeze) (Hemiptera: Callaphididae), on different walnut cultivars

Evin Polat Akkopru[1], Remzi Atlıhan[2]
[1]*University of Yuzuncu Yil, Turkey,* [2]*University of Yuzuncu Yil, Turkey*

Population growth parameters of dusky-veined walnut aphid, Panaphis juglandis (Goeze), were evaluated on five cultivars of walnut (Akca 1, Chandler, Fernette, Fernor, and Pedro) under field conditions in the Van region of Turkey in 2011. Experiments were carried out using potted walnut plants and plexiglas clip-cells (20 x 10 mm) with their upper side covered by muslin. Developmental time, survival and fecundity data were analyzed based on the age-stage, two-sex life table to take the variable developmental rate among individuals into consideration. The population growth rate of P. juglandis was significantly affected by the host plants. Due to longer immature developmental time, higher immature mortality rate and the lower total fecundity, aphids had the lowest performance on the Fernor cultivar; the intrinsic rate of increase (r =0.0997 d-1), the net reproduction rate (R0 = 5.90 offspring) and the finite rate of increase (λ = 1.1048 d-1) values were the lowest, and mean generation time (T= 17.93 d) was the longest.

Keywords:*Panaphis juglandis, walnut, life table*

Life table and predation analysis of predator-prey relationship between *Harmonia dimidiata* F. (Coleoptera: Coccinellidae) and *Aphis gossypii* Glover (Homoptera:Aphidiae)

De-Fen Mou
National Chung Hsing University, Taiwan

Life tables of the predator, Harmonia dimidiata F. and its prey, Aphis gossypii Glover, were studied using the age-stage, two-sex life table theory in order to consider the stage differentiation, variable developmental rate among individuals, and both sexes. To incorporate variation in predation rate due to the age, stage, and sex of predator, the daily number of A. gossypii preyed by individual H. dimidiata were also analyzed based on life table theory. At 25°C, the intrinsic rate of increase (r), the net reproductive rate (R0), and the mean generation time (T) for A. gossypii are 0.3953 d-1, 90.98 offspring, and 11.4 d, respectively. The values of r, R0, and T for H. dimidiata are 0.135 d-1, 283.02 offspring, and 41.6 d, respectively, when all eggs are included. Because the hatch rate of eggs of H. dimidiata varied with the age of the female, we also calculated the population parameters using only hatched eggs; the values of r, R0, and T for H. dimidiata are then 0.0904 d-1, 68.15 offspring, and 46.3 d, respectively. These results demonstrated the necessity of excluding the unhatched eggs to reveal realistic population parameters in cases where hatch rate varies with female age. The net predation rate of H. dimidiata fed on A. gossypii is 14,997 aphids. On average, 203.9 aphids are required for the production of a single fertile H. dimidiata egg. The computer simulation can be used for quantifying the number of predators necessary for successful control.

Keywords:*life table, predation rate, predator-prey relationship, Harmonia dimidiata, Aphis gossypii*

Constructing life tables for difficult to rear species: A case study of *Forcipomyia taiwana* (Shiraki) (Diptera: Ceratopogonidae)

Chih-Chung Lee
National Chung Hsing University, Taiwan

Cohort life table begins with a batch of eggs. The developmental data from egg to adult emergence were collected first, and then the fecundity data were collected from females emerged from those eggs. For the biting midges, Forcipomyia taiwana (Shiraki) (Diptera: Ceratopogonidae), oviposition data could be recorded from field-collected female adults after blood meal in the laboratory, and the developmental data from egg to adult stage could be observed as well. It is, however, difficult to get the emerged females and males under artificial condition. Therefore, the cohort life table could not be constructed due to the difficulty of mating in laboratory. In this paper, I used random sampling to construct cohort life table by linking the oviposition data of parent generation and developmental data of the offspring generation. I validate this method by using a cohort life table of Aphis gossypii. With 30000 random sampling, the means of population parameters of constructed cohorts can take the variance of fecundity database into consideration. The reproduction database of F. taiwana was recorded from field collected females during Nov. 2009 to Apr. 2010 in Taichung, Taiwan. By using this method, the intrinsic rate of increase (r), the net reproductive rate (R0), and the mean generation time (T) for F. taiwana were 0.101 d-1, 14.72 offspring, and 26.63 d, respectively. This method can be used to construct life table for difficult to rear species with the advantage of estimation the variation of population at the same time.

The temperature-dependent development and life table parameters of *Aphis gossypii* Glover (Hemiptera., Aphididae) on *Gossypium hirsutum* L. using a linear and various nonlinear models

Ismail Karaca[1], Mehmet Salih Ozgokce[2], Senay Ozger[3], Alime Bayındır[4]

[1]Suleyman Demirel University, Turkey, [2]Suleyman Demirel University, Turkey, [3]Suleyman Demirel University, [4]Suleyman Demirel University, Turkey

Development rates, survival, fecundity and life table parameters of Aphis gossypii Glover (Homoptera: Aphididae) on Gossypium hirsutum L. at five different constant temperatures (15, 22, 25, 30 and 33 °C) and 60±5% RH were studies in the laboratory. The relationships between development rate of A. gossypii and temperature were described by fitting data to six nonlinear models and a linear model. Polynomial (P4), Logan 6, Logan 10, Janish, Briere 1 and Lactin 1 nonlinear models were used. The life tables of A. gossypii were constructed at the above-mentioned temperatures, except for 33 °C. For all stages, the relationship between temperature and development rate was predicted by the models. Euler-Lotka equation was used to estimate the age-specific life table parameters. The most appropriate curves of age-specific survival rates of adults (lx) was the Weibull frequency distribution. The estimated lower development threshold and optimal development temperature for A. gossypii were 8.8 and 30 °C, respectively. Cotton aphid required 92.4 degree-day to complete the development from first instar to adult stage. During the adult stage, the number of reproduced nymphs by a female generally reached the maximum in a few days and then slowly decreased to the end of oviposition period like most insects. This relationship was described by Enkegaard equation and most appropriate curves were fitted for fecundities (mx) at different temperatures.

Life table of *Paederus fuscipes* (Coleoptera: Staphylinidae)

Lee Jin Bong[1], Kok Boon Neoh[2], Zairi Jaal[3], Chow Yang Lee[4]

[1]Universityi sains malaysia, Malaysia, [2]Kyoto University, Japan, [3]University sains Malaysia, Malaysia, [4]University sains Malaysia, Malaysia

The life table of Paederus fuscipes Curtis was studied under laboratory conditions using three field strains from Malaysia: Desa Wawasan (DW), Sri Pinang (SP), and Ampang Jajar (AJ). The total development time of pre-adult stage of DW was 17.43 ± 0.16 d, significantly different from SP (18.60 ± 0.19 d) and AJ (18.68 ± 0.22 d). Unlike SP and AJ strains, adults of DW have shorter life span. Due to shorter life span, the reproductive output of DW exhibited two peaks in age-stage specific fecundity, registering 121.28 ± 15.98 eggs compared to SP's (127.30 ± 18.01) and AJ's (147.45 ± 17.12). The intrinsic rates of increase (r) of P. fuscipes from DW, SP, and AJ were 0.0773 ± 0.0046 d?1, 0.0788 ± 0.0051 d?1, and 0.0873 ± 0.0054 d?1, respectively; and the net reproduction rates (R0) were 40.09 ± 7.39 offspring, 45.29 ± 8.74 offspring, and 42.34 ± 8.25 offspring, respectively. The mean generation time of P. fuscipes from AJ was 43.08 ± 1.07 d, which was significantly higher than that from DW (47.95 ± 1.36 d) and SP (48.57 ± 1.43 d).

Effect of host plants on life table of broad mite, *Polyphagotarsonemus latus* (Banks) (Acari: Tarsonemidae)

Patchanee Vichitbandha[1], Angsumarn Chandrapatya[2]
[1]*Kasetsart University, Kamphaeng Saen Campus, Thailand,* [2]*Kasetsart University, Thailand*

Development, longevity and reproduction of broad mite, Polyphagotarsonemus latus (Banks), on three host plants; white mulberry (Morus alba L.), basil (Ocimum basilicum Linn.), and physic nut (Jatropha curcas L.) were investigated under laboratory conditions (25.5-30.3 ℃, 44-81 %RH, 12:12 L:D photoperiod). Broad mite completed its development from egg to adult significantly slower on physic nut leaf disc (3.71 d) than on basil leaf disc (3.37 d), but not on mulberry (3.50 d). Broad mites reared on physic nut leaf disc (8.4 d) significantly lived shorter than those reared on other two host plants (mulberry, 10.9 d; basil, 11.1 d). After reached adulthood, female broad mites could stay alive alone on host plant leaf disc similar to male on the average in all host plant, and mostly produce only male (basil, 100%; physic nut, 79 %), with a few exception (mulberry, 43%). Without male, female lived 4.9 d, 7.7 d and 8.4 d and reproduced 4.5, 6.7 and 7.3 eggs per female on physic nut, white mulberry and basil, respectively. However, the intrinsic rate of increase (rm) of broad mite on basil was lower (0.0985 d-1) than on physic nut and mulberry (0.1472 d-1 and 0.2566 d-1, respectively). The net reproductive rate of broad mite were 2.39, 2.24, and 6.52 and mean generation time were 9.2, 5.4, and 8.1days, on basil, physic nut and mulberry, respectively. Adding male to female arena on physic nut resulted in higher rm (0.2221 d-1) and significantly produced more female (% female progeny, 59.2%).

Population parameters of the oriental fruit fly *Bactrocera dorsalis* (Hendel) (Diptera: Tephritidae) of different sex ratio treatments

Yu-bin Kevin Huang
Chung Hsing University, Taiwan

For a two-sex population, sex ratio plays an important role in population growth rate. In this study, I collected the life tables of the oriental fruit fly Bactrocera dorsalis (Hendel) with different sex ratio treatments. At sex ratio of 50♀:50♂, females began to lay eggs within 7 to 10 days after emergence, and mated 2.2 times during their lifespan, the net reproductive rate (R0) was 554.9 offspring, the intrinsic increase rate (r) was 0.1689 day-1, the average generation time (T) was 37.4 day. At a sex ratio of 50♀:1♂, males mated 53.3 ± 12.2 times during their lifespan, the females mated only once; both the adult pre-oviposition period and the total pre-oviposition period were longer than that of the sex ratio 50♀:50♂. At a sex ratio of 50♀:1♂, the R0 was 561.9 offspring, which is not significantly different from that of 50♀:50♂. But at 50♀:1♂, the intrinsic rate r was 0.1194 day -1, which is significantly lower than that of 50♀:50♂. The mean generation time (T) in 50♀:1♂ was 53.1 days; it was significantly longer than that of 50♀:50♂. Our results indicated that at a low male ratio, even though the B. dorsalis population had a lower intrinsic rate, the net reproductive rate was not affected. The effectiveness of a management strategy based on male annihilation needs to be further evaluated.

Life tables of the tortoise beetle, *Aspidomorpha miliaris* (Coleoptera: Chrysomelidae) on Convolvulaceae

Wen-Feng Hsiao[1], Chung-Liang Cheng[2]
[1]*National Chiayi University, Taiwan,* [2]*National Chiayi University, Taiwan*

The purpose of this study was to investigate the life cycle of the tortoise beetle, Aspidomorpha miliaris on five Convolvulaceae host-plants. The Convolvulaceae species chosen were water convolvulus (WC, Ipomoea aquatica), sweet potato (SP, Ipomoea batatas), mile a minute vine (MM, Ipomoea cairica), common morning glory (CM, Ipomoea purpurea), and littlebell (LB, Ipomoea triloba). The pre-adult stage of A. miliaris on WC, SP, MM, CM and LB lasted 41.40(±1.92), 40.63(±1.74), 41.98(±1.53), 41.03(±1.79), and 39.77(±0.81) days, respectively, at 250C. The adult longevity was 123.68(±26.63), 127.60(±19.54), 121.85(±12.86), 86.93(±9.81), and 111.08(±10.49) days, respectively, on these host-plants. The intrinsic rate of population increase (rm) was 0.04930, 0.05996, 0.05369, 0.04286 and 0.04810 and reproduction rate (R0) was 98.90, 145.87, 132.20, 50.57 and 75.60, respectively, on the five Ipomoea species. The mean generation time (T) was 93.19, 83.11, 90.97, 91.54 and 89.92 days and the finite rate of population increase (λ) was 1.0505, 1.0618, 1.0552, 1.0438 and 1.0493, respectively, on WC, SP, MM, CM and LB. All rm values were lower than 0.1. Among the host-plants, the cohort fed on sweet potato had the highest rm, R0 and λ; these values were the lowest when insects were fed on common morning glory.

Use of life tables in aphid demography and in evaluation of crop resistance

Huiyan Zhao[1], Zuqing Hu[2], Xiangshun Hu[3], Gaisheng Zhang[4]

[1]Northwest A & F University, China, [2]Northwest A & F University, China, [3]Northwest A & F University, China, [4]Northwest A&F University, China

The life table is not only important in insect ecological studies, but also an efficacious tool in the evaluation of crop resistance to insects. We can use the life table to evaluate the effects of UV-B, heavy metals, high temperatures, and pesticides on aphids. We use also life tables to differentiate the biotype of aphids and to estimate the influence of treated plants on the aphids feeding. Our results showed that the intrinsic rate of increase r, mean generation time T, and net appreciation rate R0 are important indices. They can reflect the influences of environmental factors on aphids. Furthermore, 46 germplasm resources of wheat were identified by using the life table study. Aphid-resistant cultivars or lines of wheat were selected. According to the analysis of new XZ hybrids of wheat, the resistance mechanism was tolerant of aphids.

Life tables of important medical insects

Refaat Mohamed Gabre
Cairo University, Egypt

Life tables have been used to understand survival rate and fecundity of insect population. It is the most important basis for qualitative and quantitative study of population ecology. I reviewed the life tables of a number of important medical insects, belonging to five orders; Diptera (mosquitoes, sand flies, black flies, blow flies, flesh flies, horse flies, deer flies, stable flies, and house flies), Hemiptera (bed bugs and assassin bugs), Siphonaptera (fleas), Phthiraptera (sucking lice) and Dictyoptera (cockroaches). They are important not only to human and animal health, but also to the economy. Four categories of life tables were used: (1) "Lotka" female life tables, which collected age-specific survivorship and fecundity to compute population parameters; (2) field life tables, which collected survival and fecundity under field conditions; (3) statistical life tables, which borrowed from demography and the actuarial sciences to analyze the mortality experience of cohorts, and (4) age-stage, two-sex life-tables, which take both sexes and the variable developmental rate among individuals and between sexes into consideration. While using the first three methods, the followings errors or problems were frequently noted: (a) only females were included, (b) stage differentiation could not be described, (c) survival rate and fecundity were usually based on the adult age, (d) stage-specific control strategy was impossible. Based on this review, the age-stage, two-sex life-tables are the optimal way to analyze the life table data of medical insects.

The effect of certain watermelon varieties on the biology of *Aphis gossypii* Glover (Hemiptera: Aphididae)

Yunus Bayram[1], Erol Bayhan[2]

[1]General Direc. of Agricultural Research and Policies Diyarbakır Plant Protection Research Station, Turkey, [2]Dicle University, Turkey

The development, reproduction, and population growth parameters of the melon aphid, Aphis gossypii (Glover), on four watermelon varieties were evaluated in climatic room and growth chambers. The watermelon varieties were Crimson Sweet, Crimson Tide F1, Galactica, and Surme. Significant differences in the biology of Aphis gossypii were observed. The highest fecundity was recorded on Galactica (58.97 offspring/female), followed by Crimson Tide F1 (57.80 offspring/female), Surme (57.25 offspring/female) and Crimson Sweet (57.03 offspring/female). The highest net reproductive rate was observed on Crimson Tide F1 (22.40 offspring), while the lowest was on Surme (18.61 offspring).

Consumption capacity of *Helicoverpa armigera* (Hubner) (Lepidoptera: Noctuidae) fed on asparagus determined by using the two-sex life table

Ratna Kumar Jha[1], Li-Cheng Tang[2]
[1]*Plant Protection Directorate, Nepal,* [2]*National Chung Hsing University, Taiwan*

Consumption capacity of Helicoverpa armigera (Hubner) (Lepidoptera: Noctuidae) reared on asparagus (Asparagus officinalis L.) were studied under laboratory conditions by integrating into the age-stage, two-sex life table. Development, survival, fecundity, and consumption data were analyzed by the age-stage, two-sex life table. This study indicated that asparagus is a natural but suboptimal host of H. armigera due to the poor nutritional content in its foliage and poor fitness of H. armigera fed on it. The uncertainty associated with life table parameters were estimated by using jackknife and bootstrap techniques and the results were compared for statistical inference. The intrinsic rate of increase (r), finite rate of increase (λ), net reproductive rate (R0), and mean generation time (T) were estimated by the jackknife technique to be 0.0780 day-1, 1.0811 day-1, 67.4 offspring, and 54.8 day, respectively, while those estimated by the bootstrap technique were 0.0752 day-1, 1.0781 day-1, 68.0 offspring, and 55.3 days, respectively. The net consumption rate of H. armigera, as estimated by the jackknife and bootstrap technique, was 1183.02 and 1132.9mg per individual, respectively. The frequency distribution of sample means obtained by the jackknife technique failed the normality test, while the bootstrap results fit the normal distribution well. By contrast, the relationship between the mean fecundity and the net reproductive rate, as estimated by the bootstrap technique, was slightly inconsistent with the relationship found by mathematical proof. The application of the jackknife and bootstrap techniques in estimating population parameters requires further examination.

Effect of static magnetic fields (SMF) on the viability and fecundity of aphid *Sitobion avenae* (Homoptera : Aphididae) under laboratory conditions

Juan He[1], Huiyan Zhao[2]
[1]*Northwest A & F University, China,* [2]*Northwest A & F University, China*

Using the age-stage two-sex life table, our experiment estimated the effect of two external static magnetic fields (0.176T and 0.065T) under four different exposure periods (15min, 30min, 60min, 120min), on the demography of Sitobion avenae in terms of development, fecundity and reproduction. It was demonstrated that nymphs exposed to these two magnetic fields statistically significant shorten the first instar and adult longevity, prolonged the third and fourth instar under the treatment for 0.176T-30min and 0.065T-60min in comparison with the control group. For the 0.176T-30min and 0.065T-60min, compared with the control (the first instar 4.0 d and adult longevity 8.4d), the results showed that the first instar was shortened by 1.0d and 0.9 d, adult longevity was shortened 3.9d and 3.1d; the total age of third and fourth instar were prolonged by 1.4d and 0.6d; but they were no interaction in exposure time and intensity of SMF. Lifetime fecundity of these two exposure rates were 4.6 and 0.9, or 23% and 5% of the control (19.9), but it was not showed statistical significance. The intrinsic rate of increase (r) were 0.1165 and -0.0198, net reproductive rate (R0) were 3.5 and 0.7, mean generation time (T) were 11.7d and 11.8d, and finite rate of increase (e) were 1.2382 and 0.9791 in comparison with the control group (r 0.2257, R0 19.8,T 13.2,and e 1.2531). These results can be attributed to the modulatory effect of the employed external magnetic field on development and growth regulation in the insects.

Notes on the biology of fig-tree moth *Ocnerogyia amanda* Staud. (Lepidoptera:Lymantriidae) from Erbil City, Kurdistan Region, Iraq

Wand Khalis Ali
University of Salahaddin, Iraq

This study was carried out in Erbil city for three years from 1-3-2009 to 19-11-2011 continually both in the field and laboratory belong to Directorate of Agriculture Research-Ankawa within Erbil city. The results showed seven generation per a year for the fig moth with eggs laid by a female ranged from 98 to 156 eggs, while the egg incubation period ranged from 7-12 days and the larval stage occupied 7-15 days and the pupal stage covers 7-11 days, more over the entire life cycle for all the studied generations ranged between 28 to 39 days. Also some field and laboratory observation were taken, in particular the length of duration of the separate larval instars, number of mating and number of generation per year, which seem not to have been given before in detail.

Effects of host range, mobility, and surrounding environment on spatial dynamics and movement of insect pests

Yong-Lak Park
West Virginia University, U.S.A.

Spatial and temporal distribution of insect pest is one attribute that can assist in understanding its population dynamics and management. When the spatial and temporal pattern of insect pests is described, logical hypotheses about factors driving the distribution can be explored, which leads to science-based pest management. In this study, spatial dynamics of multiple insect pests with different host range, mobility, and surrounding environment were compared. A multi-year study was conducted to characterize the spatial patterns of the insect pests by using geostatistics and spatial analysis by distance indices (SADIE). For insects with narrow host range, field-scale study was conducted with an off-set sample lattice on 8-ha farms in Iowa, U.S.A. For insects with wide host range, samples were located in multiple crops on a 12-ha farm in West Virginia, U.S.A. Geo-coordinates of sample locations were obtained with a differentially-corrected global positioning system (DGPS; Magellan MobileMapper Pro, Santa Clara, CA). Spatial data obtained from this study were used to generate distribution maps of the insects in two ways: contour mapping with geostatistics and patch/gap mapping with SADIE. This study elucidated how insect pests move within and among commodities and how spatial dynamics of the insect pests were affected by mobility of the insect pests and availability of host plants. Different management options based on spatial dynamics, mobility, and host range of insect pests are discussed in this presentation.

Entomological-radar monitoring of insect pest population movements

Vincent Alistair Drake[1], Haikou Wang[2]
[1]*University of New South Wales and University of Canberra, Australia,* [2]*Australian Plague Locust Commission, Australia*

The inland of south-eastern Australia encompasses extensive croplands and rangelands with no major barriers to aerial movement. This region hosts several migratory insect pests, including Australian plague locusts and several noctuid moth species. Populations arising in the rangelands following characteristically irregular rains migrate into cropping areas, causing damage that varies from year to year both in its intensity and in the region affected. Since 1999, insect migrations within this region have been observed with two fully-automated Insect Monitoring Radars (IMRs) located 300 km apart. These units operate throughout each night and detect individual insects as they pass directly overhead. A summary of the observations is available to locust forecasters the next morning, and a full data archive is maintained to allow more complete retrospective analyses. The IMR signals yield estimates of each target's height, speed and direction of movement, and alignment, along with measures of size and shape, and sometimes also the wing-beat frequency. The last few quantities are used to assign a target to one of a small number of classes, each representing a group of species - larger orthopterans, large moths, small moths, etc. Ancillary survey and trapping may identify the species predominating a class on particular nights. Significant movement events can be recognised for each class, and their intensities, directions, and spatial scales estimated. Statistics of these and other measures of migratory activity derivable from the radar data can be drawn on by pest forecasters and those making decisions about whether, when, and where to control.

Analysis of spatial distribution of greenhouse insect pests in Korea

Jung-Joon Park[1], Kijong Cho[2]
[1]*Korea University, Republic of Korea,* [2]*Korea University, Republic of Korea*

Analysis of Spatial distribution of two greenhouse insect pests, greenhouse whitefly and western flower thrips were evaluated using variogram models and spatial analysis of distance indices (SADIE) in Korea Variogram analysis was used to estimate and compare the attractive distances of two different sizes of yellow sticky traps for sampling whitefly adults in four commercial cherry tomato greenhouses. The patch size of whitefly immatures between plants was also estimated using visual counts. For whitefly adults on sticky traps the range of variogram was not considerably different between two trap sizes, which indicated that the attractive distances of the two different yellow sticky traps were very similar. The ranges of the variograms for the visual count of immatures on plants were always less than those for adults, indicating that the attractive distance of the traps for whitefly adults extends beyond the patch size for immatures on cherry tomato plants. The spatio-temporal dynamics of immature and adult of western flower thrips were analyzed based on the classical indices and SADIE. Based on the dispersion indices, thrips were found to be aggregated in both greenhouses. The SADIE index of aggregation and association probability were estimated and compared between stages and between sampling times. There were substantial spatial associations between adults and immatures each week; however, the temporal stability of the spatial patterns of adults and immatures decreased over time. The spatial patterns of thrips and their associations presented here provide the baseline information necessary to understand and predict plant damage and thrips dynamics.

Integrated Pest Management

Influence of predator-avoidance behavior on the movement patterns of whiteflies in greenhouse

Doo Hyung Lee[1], Jan Nyrop[2], John Sanderson[3]
[1]USDA-ARS, U.S.A., [2]Cornell University, U.S.A., [3]Cornell University, U.S.A.

This study focused on destructive crop pests, whiteflies (Hemiptera: Aleyrodidae), as a model system to explore how natural enemies can influence the efficacy of pest management programs. Towards this end, the study asked how predator-avoidance behaviors by whiteflies can improve and/or adversely impact the outcome of habitat manipulation and biological control. A series of manipulative experiments were conducted to test whether 1) predator-avoidance behaviors by whiteflies can be used as 'push component' to enhance trap cropping and 2) the predator-avoidance behaviors can unintentionally elevate pest dispersal from heavily-infested areas into uninfested habitats. First, we investigated under a trap crop system whether differential predation risks among plants influence host choice patterns of adult whiteflies, Bemisia argentifolii, between cash crop (poinsettia) and trap crop (cucumber). Among three natural enemy species tested, the predatory beetle, Delphastus catalinae (Coleoptera: Coccinellidae), on poinsettia induced significantly more whiteflies to abandon the cash crop and move onto the enemy-free trap crop. Second, we examined how adult whiteflies modulate resource uses in a response to the predatory beetles across different spatial scales. The results demonstrate that the magnitude of predator-avoidance behaviors by whiteflies could vary depending on available habitat scales. The presence of predators resulted in an elevated pest dispersal into new habitat areas within cucumber plant, whereas this predator effect was not measurable at among-plant movements by whiteflies. This study supports that non-consumptive effects of natural enemies should be further investigated to better understand these unexplored pathways between predator-prey interactions when designing and implementing bio-based management tactics.

Site specific management of insect pests of elm trees in the University of Tabriz campus

Roghaiyeh Karimzadeh[1], Mir Jalil Hejazi[2], Shahzad Iranipour[3]

[1]University of Tabriz, Iran, [2]University of Tabriz, Iran, [3]University of Tabriz, Iran

Elm trees are important landscape trees in most parts of the world including Iran. Like other plants many pests injure elms every year. Outbreaks of sucking insects weaken the trees and produce large amounts of honeydew contaminating clothes of passersby and cars parked under the trees. High volumes of broad spectrum insecticides are used to control these pests. The main objective of this study was site specific management of the elm trees using the University of Tabriz campus as a pilot. For this purpose, the campus was divided into 60×60 m grids and one tree was chosen randomly from each grid. Geographic coordinates of the selected tree was saved in a hand held GPS. The trees were sampled before spraying. Each sample consisted of a 30 cm branch terminal. At least eight samples were taken from each tree in four directions and two canopy levels. The number of leaves and all insects in the samples were recorded. The data were analyzed and the spatial distribution of the pests was determined. The regions with high populations were determined on the map. The trees with higher populations were sprayed with abamectin, imidacloprid and dimethoate and their lethal effects were compared. Each treatment consisted of four trees and three untreated trees were considered as control. The trees were sampled 1, 2, 4 and 7 days after treatment. Site-specific application reduced the insecticide input considerably. The results indicated that all insecticides reduced the pest populations significantly compared with control.

Spatial movements and dynamics of epidemic bark beetles

Bjørn Økland[1], Olav Skarpaas[2], Christo Nikolov[3]

[1]Norwegian Forest and Landscape Instutute, Norway, [2]Norwegian Institute for Nature Research, Norway, [3]National Forest Centre - Forest Research Institute, Slovakia

The role of movements for spatial dynamics differs between the case of invasive bark beetles arriving in low numbers and bark beetles at epidemic densities. Two studies of bark beetles may illustrate some of the differences: (1) We use a generic model for the first step of the invasion process for bark beetles that may arrive in timber import to Scandinavia. Our results suggest that detection of dispersal from storage to forests will be difficult even when pheromone traps are used. This may imply that management actions are not to be deferred until after detection in nature, as the pest species is already established and eradication may be too late. However, pre-emptive measures reducing propagule pressure at one or several stages of the introduction process may strongly reduce introduction risk. (2) We model the sizes of outbreak patches by comparing model simulations based on dispersal of bark beetles and patterns of outbreak forest patches killed by Ips typographus in the High Tatra Mountains of Slovakia. Since the relative importance of attraction and site specific characters is unknown, we included three model variants to simulate dispersal and development of outbreak patches. For the highly mobile bark beetles, our results indicate that distance to previous outbreak patches and their sizes are only weak predictors of the sizes of new outbreak patches.

A simulation model to predict the potential spread of the pine wood nematode, *Bursaphelenchus xylophilus* over a range of scales

Christelle Robinet[1], Jianghua Sun[2], Richard Baker[3], Hugh Evans[4], Alain Roques[5]

[1]INRA, France, [2]Chinese Academy of Sciences, China, [3]Food and Environment Research Agency, United Kingdom, [4]Forestry Commission Research Agency, United Kingdom, [5]INRA, France

The pine wood nematode, Bursaphelenchus xylophylus, is the causal agent of the pine wilt disease. The species is native to North America where it is only a minor pest, mainly on non-native tree species. It has been introduced to several Asian countries (Japan, China, Taiwan, Korea) and to Europe (Portugal with some records in Spain). In most cases, the nematode has spread very rapidly despite control measures, and caused extensive damage to forests. If tree species are susceptible and climate is suitable, then the pine wood nematode can cause pine wilt and trees can die within a few weeks. Within forests and woodlands, the nematode is carried from one tree to another by adult beetles of the genus Monochamus whereas it can spread over long distances as a result of accidental transportation of infested materials. It is therefore important to understand the dispersal mechanism of the nematode and to determine the areas at risk. Here we present a spread model which combines short distance spread (to describe the dispersal of the vector) and long distance spread (to describe human transportation). This model was successfully used to predict the potential range expansion of the pine wood nematode and pine wilt disease in China. It also provides indications of which European ports are the most at risk for nematode introduction arising from international trade. The potential spread in Europe from the present invaded area in Portugal will be determined more accurately in the frame of the EU project REPHRAME (2011-2014).

Putting the brakes on the European corn borer cycle in the US: Bottom-up effect of genetically modified (GM) maize damps cycle amplitude

James R Bell[1], Eric C. Burkness[2], Alice A. Milne[3], David W. Onstad[4], Mark Abrahamson[5], Krista L. Hamilton[6], William D. Hutchison[7]

[1]Rothamsted Research Harpenden AL5 2JQ, United Kingdom, [2]University of Minnesota, U.S.A., [3]Rothamsted Research Harpenden AL5 2JQ, United Kingdom, [4]University of Illinois Urbana, U.S.A., [5]Minnesota Dept. of Agriculture, U.S.A., [6]Trade and Consumer Protection, U.S.A., [7]University of Minnesota, U.S.A.

In this presentation we discuss the spatial ecology of the European corn borer [Ostrinia nubilalis (Hubner) Lepidoptera: Crambidae] that once so devastated maize crops it cost the American economy an estimated $1 billion per annum. The population of O. nubilalis cycles as a result of a density dependent relationship with entomopathogenic parasite, Nosema pyrausta (Microsporida: Nosematidae). We consider whether landscape-level manipulations can be used to restrict the cycle amplitude of O. nubilalis beyond the limits of its natural regulator. We test for the bottom-up effect of genetically modified (GM) maize engineered to express Bt transgenes (i.e. Cry1Ab) that has been used across the Corn Belt since 1996. Time series from Minnesota (1963-2009) and Wisconsin (1964-2009) were analyzed using non-linear regression and wavelet analyses complemented with a spatial spline and mechanistic model to demonstrate the differences in population dynamics of O. nubilalis between the two states. The extent of regime change in the US Corn Belt where rates of transgenic Bt maize adoption varied were statistically quantified: the introduction of Bt maize explained cycle damping when the adoption of the crop was high (Minnesota) but oscillations were damped but continued to persist when Bt maize was used less intensely (Wisconsin). We conclude that host plant quality is key to understanding both epidemic persistence and the success of intervention strategies. In particular, the dichotomy in maize management between states is thought to limit the spatial autocorrelation of O. nubilalis to a correlation length of 275 km.

Lepidopteran pest pressure in stone fruit tree orchards in Korea compared to other countries

Chuleui Jung[1], Jeong Joon Ahn[2], Seon Ah Jeong[3], Ialit Prasad[4], Hyangmi Kim[5], Soonwon Lee[6]

[1]Andong National University, Republic of Korea, [2]Andong National University, Korea, Republic of, [3]Andong National University, Republic of Korea, [4]Andong National University, Republic of Korea, [5]Korean fruit pest forecasting research center, Republic of Korea, [6]Korean fruit pest forecasting research center, Republic of Korea

Apple, pear, peach and plum are the main stone fruit trees in Korea. Fruit boring lepidopteran pests are the major concerns for growers not only for the domestic market but also for exporting. Carposina sasakii, Grapholita molesta are the major fruit boring pests. Researches on pest population dynamics and managements are presented. Seasonal cycle and pattern of pest occurrence was not quite related to the tree phenology. However the annual population size of both pests was different among tree species. Recently, Grapholita dimorpha is increasing its awareness in various fruit orchards. From the published data and our recent sampling study, pest pressure of Oriental fruit moth, peach fruit moth and codling moth including G. dimorpha was compared relative to the management practices. Further, critical information needed for developing area-wide management concept was discussed, such as dispersal capability, insecticide resistance and habitat management for natural enemies. .

Reduced pest status of lightbrown apple moth (*Epiphyas postvittana*) and native leafrollers (Lepidoptera: Tortricidae) on apple orchards in New Zealand

Peter Leonard Lo[1], Jim Walker[2]
[1]Plant & Food Research, New Zealand, New Zealand, [2]Plant & Food Research, New Zealand

Leafrollers are important pests of tree and vine fruit crops in New Zealand. The dominant species is the ubiquitous lightbrown apple moth (Epiphyas postvittana), followed by endemic Ctenopseustis spp. and Planotortrix spp. Up to the mid 1990s, leafrollers were one of the most important pests on apples, but their status has since changed to being of minor economic consequence in integrated fruit production (IFP) programmes. This change during the past 30 years was documented in four ways: pheromone trap catches of adult males, searches for larvae and pupae, quarantine pest inspection records of packed fruit, and examination of harvested fruit that had not received leafroller-active insecticides. Until the late 1990s, apples were grown under a calendar-based programme of broad spectrum pesticides, with up to nine applications per year. Leafrollers had resistance to organophosphate insecticides, there was minimal biological control and up to 47% of fruit was damaged in managed orchards. Several larval and pupal parasitoids were introduced in the 1980s, and an IFP programme was implemented in the late 1990s where organophosphates were replaced with selective products. Today, pheromone trap catches and larval finds of lightbrown apple moth are greatly reduced, although its wide host plant range means it is still relatively abundant. IFP orchards receiving 1-2 leafroller insecticides annually typically have <0.5% fruit damage at harvest, and even on trees with no insecticides, infestations are generally <3%. Leafrollers are currently managed to an extremely high degree by a combination of highly effective selective insecticides supplemented with improved biological control.

The impact of invasive brown marmorated stink bug, *Halyomorpha halys* on IPM programs in eastern US fruit orchards

Greg Krawczyk[1], Larry A. Hull[2], David J. Biddinger[3]
[1]*Penn State University, U.S.A.,* [2]*Penn State University, U.S.A.,* [3]*Penn State University, U.S.A.*

Brown marmorated stink bug, BMSB, Halyomorpha halys (Stal) (Heteroptera: Pentatomidae) is an exotic insect pest introduced into North America around mid 1990's. Currently, the BMSB populations are reported from over 30 states and Canada. The biggest economic impact of this invasive insect is observed on various agricultural and horticultural crops grown in the mid-Atlantic region of US. During last few seasons, some stone and pome fruit orchards experienced up to 60 percent loss of fruit value due to the BMSB feeding. At this time, in the absence of specialized effective natural control agents, only the use of broad spectrum insecticides provides adequate control of BMSB infestation. However, additional applications of insecticides, not normally used (or recommended) in our fruit IPM system, already are causing an increase in the number of observed outbreaks of secondary fruit pests such as mites, wooly apple aphids or scale insects. There is immediate and urgent need to develop and evaluate other, alternative methods and products that are effective against BMSB so softer, more sustainable methods can be utilized in the future. In our presentation we will attempt to present the established pre-BMSB fruit IPM system in Pennsylvania orchards and the actual and potential consequences of this accidental introduction of a single invasive pest species on common fruit IPM practices.

Assessment of mass trapping with kairomones and pheromones against the apple clearwing moth, *Synanthedon myopaeformis*

Maya Evenden[1], V. Marius Aurelian[2], Gary Judd[3]
[1]*University of Alberta, Canada,* [2]*University of Alberta, Canada,* [3]*University of Alberta, Canada*

Semiochemical-baited mass trapping was tested against the apple clearwing moth (Synanthedon myopaeformis (Borkhausen) using pheromone-and kairomone-baited traps. Mass trapping significantly reduced the number of moths captured in assessment traps positioned in pheromone-treated but not kairomone-treated plots. Pheromone and kairomone-based mass traps removed more moths with increasing trap density. Kairomone mass trapping removed male and female moths and removed as many or more individuals from the population than pheromone-based mass trapping. Traps targeting the apple clearwing moth also captured non-target arthropods. More non-target arthropods were captured in kairomone-baited traps than pheromone traps. More non-target arthropods and a greater diversity of non-target arthropods were captured in organic than conventional orchards. Potential effects on non-target arthropods should be considered in future development of semiochemical-based management of the apple clearwing moth.

Considerations in the design of mass trapping or lure and kill for pest management

David Maxwell Suckling[1], John M. Kean[2], Lloyd D. Stringer[3], AM. El-Sayed[4], P. Lo[5], V. Bell[6], DJ. Rogers[7], JTS. Walker[8]

[1]The New Zealand Institute for Plant & Food Research Limited, New Zealand, [2]AgResearch, New Zealand, [3]The New Zealand Institute for Plant & Food Research Limited, New Zealand, [4]The New Zealand Institute for Plant & Food Research Limited, New Zealand, [5]The New Zealand Institute for Plant & Food Research Limited, New Zealand, [6]The New Zealand Institute for Plant & Food Research Limited, New Zealand, [7]The New Zealand Institute for Plant & Food Research Limited, New Zealand, [8]The New Zealand Institute for Plant & Food Research Limited, New Zealand

Mass trapping and lure and kill are related tactics for male removal using female sex pheromones or other semiochemicals, and can offer pest management benefits. Mass trapping enables researchers to directly count the insects removed but the cost of traps and labour can be limiting. Lure and kill offers a solution to this but it can prove difficult to assess population suppression, due to competition between traps and wild female insects. Insights gained from mass trapping can indicate whether potential exists for lure and kill systems to be developed. A theoretical framework has been developed and tested on four different orders of pest insects (Lepidoptera, Homoptera, Diptera and Thysanoptera), in order to determine whether a standard protocol could be used to advance the development of mass trapping and lure and kill systems. The system is based on an assessment of trap competition and takes into account trap spacing, lure strength and other factors.

Biologically based management of Asian citrus psyllid (ACP) *Diaphorina citri* to reduce spread of huanglongbing in Florida

Jawwad A. Qureshi[1], Philip A. Stansly[2]
[1]*University of Florida/IFAS, U.S.A.*, [2]*University of Florida/IFAS, U.S.A.*

Diaphorina citri Kuwayama vectors Candidatus Liberibacter asiaticus, a bacterium which causes Asian form of "huanglongbing" (HLB) or citrus greening disease. ACP and HLB discovered from Florida in 1998 and 2005, respectively, are now well established and pose a serious threat to the citrus industry. Vector control is critical to reducing the incidence of HLB. Biological control is critical to manage this pest disease complex. Field studies in 2006-2007 showed 5-27 fold reduction in psyllid populations mainly by predacious insects and spiders. Mature citrus trees in Florida produce most new growth in spring, followed by summer and fall which is attractive to pests and beneficial insects. Therefore, foliar sprays of broad spectrum insecticides applied to mature trees in winter were evaluated in commercial citrus as tactic to reduce psyllid populations and insecticide use in spring and summer. Single sprays of chlorpyrifos, fenpropathrin and oxamyl in January reduced adult psyllids an average of 10-15-fold over 5-6 months compared to untreated trees, respectively, without additional sprays. Spiders, lacewings, and ladybeetles were equally abundant during the growing season in both treated and untreated trees. This tactic has been adopted area-wide to manage psyllid in Florida. For additional suppression of psyllid we are mass producing and releasing Tamarixia radiata, an ectoparasitoid of ACP that we imported from Pakistan, South China, and North Vietnam in 2008 and already established strain imported from Taiwan and South Vietnam in 1999. The repeated releases of these parasitoids in citrus groves are contributing to overall reduction in psyllid population.

New emerging insect pests and their management strategies in citrus orchards in Jeju, Korea

Dong-soon Kim[1], Yong Seak Jang[2], Seong Hyuk Kang[3], Su Bin Kim[4], Yong Geun Kim[5]

[1]Jeju National University, Republic of Korea, [2]Jeju National University, Korea, Republic of, [3]Jeju National University, Republic of Korea, [4]Jeju National University, Republic of Korea, [5]Jeju National University, Republic of Korea

The arthropod pest status in citrus orchards has been largely changed since last decades in Jeju, Korea; probably caused by climate changing. We will introduce two new insect citrus pests of Epuraea domina Reitter (Coleoptera: Nitidulidae) and Scirtothrips dorsalis Hood (Thysanoptera: Thripidae) in this presentation. E. domina has been known as a pollinator in citrus orchards. During pollination activity, however, the appendages such as legs cause a scratch on the ovary of citrus flower, and it develops later to a corky scar on citrus fruits at harvest resulting in deterioration in the fruit quality. This insect has a very characteristic life cycle, showing winter breeding behavior. E. domina adults spend summer season in mountainous habits and migrate to citrus orchards in late autumn to lay eggs in soil during the winter. The hatched larvae feed on fallen citrus fruits during the winter to develop pupae. The pupae emerge to new adults in mid to late May to feed pollens and nectar in citrus blooming season; followed by migration again to mountainous habitats in early summer. Because they reproduce during the winter, weather condition in winter was essential for the population increase. S. dorsalis induces silver-grey, dark brown scaring or dark brown discolored damages on Mandarin citrus fruits in Korea, which has occurred in Jeju Island since 2007. Also, this pest has been known as causing economic loss on cash crops worldwide including Unite States. The population dynamics will be presented in relation to survival on host plants and weather conditions.

Progress in the development of an in-canopy fixed spraying system for high-density apple orchards

Arthur M. Agnello[1], Andrew J. Landers[2]
[1]*Cornell University, U.S.A.*, [2]*Cornell University, U.S.A.*

Introduction: Pesticide application to tree fruits using airblast sprayers can be inefficient and inaccurate, resulting in spray drift, off-target contamination, and ineffective pest control. A spray system fixed into the tree canopy was used to apply pesticide sprays to a commercial planting and compared with a conventional sprayer. Methods: A high-density apple planting (0.5 ha) received all its pesticide sprays through a system of microsprinkler nozzles attached to polyethylene tubing running along the tops of tree canopies and supplied by a central tank and pumping station. In initial trials, insect and disease control, and spray deposition data were compared with those in a section of orchard treated using a tractor-pulled airblast sprayer. An improved design uses tubing reservoirs at each spray head, which are first filled with sufficient spray solution to adequately wet the surfaces of the foliage and fruits below the nozzles, and compressed air is then used to completely blow out the spray. Results: In the initial trials, sprays were applied quickly and efficiently, each taking only a few minutes to completely cover all the trees in the fixed-spray plots. In-season sampling sessions revealed comparable control levels of insects and diseases in both spray treatments. Continuing work will focus on optimizing efficiency of spray coverage and distribution using practical and economical system design considerations to encourage adoption by the fruit producing industry. Conclusions: A fixed nozzle arrangement could offer benefits in pesticide application efficiency and accuracy while maintaining crop protection efficacy and production quality in modern apple plantings.

IPM on top fruit in Italy: State of the art and outlook

Edison Pasqualini[1], Claudio Ioriatti[2], Fabio Molinari[3]
[1]University of Bologna, Italy, [2]Fondazione Edmund Mach, San Michele all'Adige, Italy, [3]University of Piacenza, Italy

IPM was born in Italy in 1972, after ten years of entomological researches and investigations aimed to study the behaviour of the most important species of pest and beneficial insect and to assess the response to different control techniques. In those years, many demonstration projects began and achieved significant results and a substantial decrease in number and toxicity of the insecticides used. In the eighties, those projects turned into programs for Integrated Pest Management (IPM), and over time other fruit and horticultural crops joined to the programs. These crops are currently regulated by Integrated Production Disciplinary (DPI), which defines the crop growing techniques in all agronomic aspects and control strategy (sensu lato). The environmental factors were decisive in implementing IPM, especially since the early nineties, following specific Community Directives, which over time have allowed to increase IPM techniques until they become mandatory in Europe in 2014 (Law 128/09). The Directive emphasize the training and transfer of all the knowledge related to the proper use of insecticides, the general principles of IPM and the risk indicators that allow to assess the way in which chemicals are used. The market demands for productions without or with a limited number of residues might become a factor conditioning the IPM, stimulating, however, the improvement.

A 20 year evolution of pear pest management in the Western United States

Robert Van Steenwyk[1], S.C. Welter[2], J.E. Dunley[3]

[1]University of California, U.S.A., [2]San Diego State University, U.S.A., [3]Wilber-Ellis Co, U.S.A.

The history of the evolution of pear pest management in the Western United States from sole reliance on broad-spectrum organophosphate and pyrethroid insecticides to a codling moth pheromone mating disruption based system with supplemental reduced risk insecticides will be discussed in relation to causal factors responsible for this dramatic shift. The impact of this transition on key secondary pests and on resurgence of dormant pests will be discussed along with future directions of the Western United States pear pest management.

Ecological control of native insect pests based on insect population genetics in regional rice IPM

Jichao Fang
Jiangsu Academy of Agricultural Sciences, China

Yellow stem borer (YSB), Scirpophaga incertulas Walker, and striped stem borer (SSB), Chilo suppressalis Walker, are prevalent and destructive natives generally concurring in extensive rice-planted area along the Yangtse River of China. But in some patches of the area the either or both have occurred little for years. What acts as naturally sustained counteraction on the pests there? Our investigation found that, 1) breadth of yearly temporal niche in each of 11 YSB populations was greatly jumpy during past decades (for example, 0~0.68 or 0.43±0.19 in Suzhou of Jiangsu province for the last 34 years) corresponding to fluctuation of the population size in different years and significantly lower than that in the same site SSB (0.60~0.87 or 0.73±0.09), whereas breadth of the spatial niche is relatively much stable and high in that there existed little resistance of rice varieties and low parasitic rate (27.8% ~40.3%) of the Trichogramma japonicum Ashmead to YSB. Evidently the temporal niche of YSB is susceptible (but the spatial resistant) to alteration of the coevolutionary factors,while that of SSB quite stable. 2) The SSB stable niche derived partly from distinct temporal ecotypes including earliest (E) and later (L) types, to sampled individuals of which all showed specific DNA SCAR or AFLP markers (L820 to the L-type and E335 to the E). 3) The YSB susceptible niche broadened only providing rice duration in field extended longer than YSB yearly occurring duration or the latter was elastically compressible in certain zones or years with an incomplete generation of YSB.

Ecological regulatory mechanism of temperature on population size in *Laodelphax striatellus*

Xiangdong Liu[1], Aimin Zhang[2]

[1]*Nanjing Agricultural University, China,* [2]*Nanjing Agricultural University, China*

Temperature is one of the key factors that influence the occurrence of Laodelphax striatellus (Fallen), especially in the winter and summer. However, the specific biological responses of L. striatellus to high temperature were unclear. The effects of duration of high temperature (33 ºC) on life-history traits and morphological variation were studied using 27 ºC as the control. Exposure of adults for one day during oviposition stage led to a very low survival of nymphs. The average longevity of L. striatellus exposed for 1-31 days from oviposition was significantly longer than that of the control. Short-term (1-5 days) heat exposure from the 3rd instar nymphs did not significantly influence eclosion, but exposure from the 4th instar nymphs significantly increased eclosion. Lifespan from egg to adult was significantly lengthened when the 3rd instar nymphs were exposed to heat for 2~15 days, or the 4th instar exposed for 10 days. The preoviposition period were prolonged by the heat exposure from the 3rd or 4th instar nymphs. Short-term heat exposure of less than three days from the 3rd or 4th instar nymphs did not restrict fecundity, but when the exposure duration exceeded five days the total eggs per female and hatchability decreased. Exposure to high temperature increased the brachypter rate of adults and decreased fluctuating asymmetry in several nymphal morphologic traits. Low survival and slowing development under heat exposure resulted in population decline in the summer, and the relatively high fecundity, brachypter rate and symmetry led to quick revival in the autumn.

Biological and ecological control of the brown planthopper in South China

Wenqing Zhang[1], Guren Zhang[2], Dexiang Gu[3]

[1]Sun Yat-sen University, China, [2]Sun Yat-sen University, China, [3]Sun Yat-sen University, China

A community's capacity for development resides in its species pool. Species pool in rice ecosystem includes ridges of rice fields, roadsides, non-rice crop habitats and fields with no crops. Our results showed that the dominant species of natural enemies in ridges were often the same as those during reestablishment period of arthropod community in rice fields. In Guangdong Province, the spider Ummeliata insecticeps first moved from species pool into rice fields in early rice season and became the dominant species of the arthropod community. It had the biggest time-space niche overlapping value with rice planthoppers (including the brown planthopper Nilaparvata lugens), followed by Pirata subpiraticus. As one of the model examples, the rice IPM program in Dasha Township of Guangdong Province, located in N23°19', E112°40', started in 1973 in 1.6 ha rice field and reached 4000 ha in 1975. This long-term program has been very successful and achieved significant long-term benefits. In order to ensure the program successful, IPM experts teach farmers basic IPM knowledge such as distinguishing insect pests and natural enemies in a field farmer school (FFS); several biological and ecological control measures have been used for more than 30 years.

Diversity analysis of symbiotic bacteria in *Nilaparvata lugens* with different virulence

Wang Weixia[1], Fu Qiang[2]

[1]China National Rice Research Institute, China, [2]China National Rice Research Institute, China

Symbiotic bacteria are key players in insect-plant interactions influencing many aspects of insect ecology and playing a key role in shaping the diversification of many insect groups. The brown planthopper (Nilaparvata lugens Stal, Homoptera: Delphacidae) is an important pest of rice, which feeds mainly on the rice stems and sucks assimilates from the phloem. Different virulent population of brown planthopper has proven different virulent to the resistant rice varieties. Analysis of the diversity of symbiotic bacteria in Nilaparvata lugens with different virulence will be helpful for understanding the mechanism of virulence differentiation of brownn planthopper. Investigations of the diversity of bacterial communities associated with three virulent labortory populations(TN1,Mudgo and ASD7) and Zhejiang field population of the BPH were made using 16S rDNA-RFLP. Sequence similarity of 97% was used as the definition of operational taxonomic unit (OTU). We found the BPH harbours a variety of symbionts which belonged to 23 OTU including intracellular symbiotic Arsenophonus, Wolbachia and extracellular symbiotic Acinetobacter, Serratia sp., Arthrobacter sp., Chryseobacterium, and other uncultured bacterium. The densities of different symbiotics in different virulent population were analysed by real-time quantitative PCR with genus-specific primer. The results showed that the amount of Arsenophonus in TN1 population was higher than in other populations. The rate of Arsenophonus infection was 53.0% and 2.0% in TN1 and Mudgo population, respectively. Compare to the subpopulation

Recent advances in the management of insect pests of rice in the USA

Michael Joseph Stout
LSU AgCenter, U.S.A.

The two most important insect pests of rice in the U.S. are the rice water weevil, Lissorhoptrus oryzophilus, and the rice stink bug, Oebalus pugnax. There have been a number of important recent advances in the management programs for these two insects. An overview of these recent advances will be presented. Topics will include the use of seed treatment insecticides, development of thresholds, and the integration of constitutive and inducible plant resistance into management programs.

Use of natural enemies as a bio-indicator for assessing environmental soundness of agricultural practices in rice paddies

Takatoshi Ueno
Kyushu University, Japan

Rice production in paddy fields can depend on pest control by natural enemies, in particular, when environmentally sound farming is applied. Maintaining the diversity and abundance of beneficial natural enemies should therefore be key to improving the productivity and sustainability in rice paddies with environmentally sound practices, and may also improve their function as an important habitat for endemic species living in wetland environments, many of which are now endangered or threatened. Use of natural enemies as indicator species to monitor and evaluate environmental soundness of farming practices will be a useful tool to promote sustainable rice production and conserve other valuable species, if the abundance and diversity of natural enemies can reflect farming practices and general biodiversity in rice paddies. Here I focus on arthropod natural enemies in rice paddies and examine the relationships among selected natural enemy species, farming practices (insecticide & manure applications) and general biodiversity. The diversity of parasitoids and predators reflected farming practices (e.g., pesticide and mature use) and the diversity of neutral species. Some of natural enemy species were found useful to assess general diversity and farming practices. The results have demonstrated that several species of parasitoid wasps and spiders are good biological indicators to monitor and assess biodiversity and environmental soundness of practices in rice paddies. Such bio-indicators can be used just like a 'bathroom scale' to know the healthiness of rice paddies.

Resistance management for planthoppers and leafhoppers in South East Asia: Challenges and opportunities

Finbarr Horgan
International Rice Research Institute, Philippines

Host-plant resistance has been the main focus for sustainable hopper management in rice for the last several decades. Currently over 70 resistance loci have been identified in rice and many have associated DNA markers that can be used in marker-assisted breeding programs. However, hoppers are known to quickly adapt to resistant varieties and resistance genes. This talk reviews the knowledge gained from over 30 years of research into hopper adaptation and highlights the challenges and opportunities for developing resistant varieties and reducing the incidence of hopper damage to rice. Patterns in adaptation differ considerably between planthoppers and leafhoppers and, though adaptation is often quicker in leafhoppers compared to planthoppers, results suggest that resistant varieties may be more durable against the former. It is clear that increasing hopper virulence is rapidly depleting the utility of available resistance loci in rice and that a coordinated attempt to manage virulence at a regional scale will be required to guarantee the success of future breeding programs.

Enhancing biological control of rice planthopper pests by ecological engineering in China

Zhongxian LV[1], Pingyang Zhu[2], Guihua Chen[3], KL Heong[4], GM Gurr[5]

[1]Zhejiang Academy of Agriculture Sciences, China, [2]Zhejiang Academy of Agriculture Sciences, China, [3]Plant Protection Station, China, [4]International Rice Research Institute, Philippines, [5]Charles Sturt University, Australia

The effects of planting sesame on the bunds of rice fields on biological control of rice planthoppers was conducted in Jinhua, China. A 35ha experimental site was divided into two parts, in which 8 ha was established as an ecological engineering area with a total of 600 m2 of sesame planted on bunds, preserving biodiversity in non-rice habitats and reducing pesticide use. A 27 ha area was managed according to normal farm practice with conventional insecticidal control. Numbers of Mymaridae on yellow sticky traps in eco-engineering fields were at least four greater times than that in farmers' fields. Differences were especially great, up to 100 fold higher, in samples taken after pesticide application in the farmers' fields. The number of invertebrate predators including odonata was significantly higher in the eco-engineering area than the farmers' fields. Frogs too were much more abundant in the eco-engineering area. In contrast to the absence of use of pesticides in the eco-engineering areas, the conventionally managed comparison fields required spraying in mid-September to control escalating numbers of planthoppers. The number of planthoppers in the eco-engineering fields remained low. Results show that planting sesame on the bunds of rice fields to provide floral resources, combined with preserving areas of non-crop vegetation and withholding insecticides can increase natural enemy numbers and activity, translating to effective biological control of rice planthoppers. This work constituted one replicate block in a much larger experiment that extends across several countries and in which similarly positive results are being

Horizontal webs of *Tetragnatha* spiders enhance biological control of insect pests by spiders in organic paddy fields

Mayura Takada[1], Tetsuya Kobayashi[2], Akira Yoshioka[3], Shun Takagi[4], Izumi Washitani[5]

[1]*Obihiro University of Agriculture and Veterinary Medicine, Japan,* [2]*National Institute of Agrobiological Sciences, Japan,* [3]*University of Tokyo, Japan,* [4]*University of Tokyo, Japan,* [5]*University of Tokyo, Japan*

Our observational study indicated that Tetragnatha spp. spiders, abundant in organic paddies, suppress a mird bug density and its damage level (Takada et al. 2012). However, the molecular gut content analysis showed that only a small proportion of the spiders fed on the bugs (Kobayashi et al. 2011). In order to understand how the cascading effect by Tetragnatha spp. spiders is enhanced, the following hypothesis was examined. The mirid bug Stenotus rubrovittatus, a major rice pest in Japan, usually remains in the upper layer of paddies to feed on rice ears. However, the mirids are frequently observed falling to the bottom layer of paddies after becoming tentatively trapped by horizontal webs of Tetragnatha spp. spiders. Bugs falling to the bottom layer are likely to be predated by ground-dwelling predators. It is hypothesized that Tetragnatha spp. spiders facilitate bug predation by wolf spiders through trait-mediated effects, in which their horizontal webs force the bugs onto the ground and thereby into the hunting zones of wolf spiders. Molecular gut content analysis of 619 wolf spiders revealed that the number of wolf spider individuals that tested positive for mirid bug predation increased significantly with Tetragnatha spp. density in the paddies. We also observed a positive relationship between Tetragnatha spp. density and total cover by their webs in paddies. We identified the potential for an unexpected interaction between an insect pest and ground-dwelling spiders that usually inhabit different microhabitats in paddy fields by focusing on trait-mediated effects of webs built by Tetragnatha spp. spiders.

Integrated Pest Management

Genetics and breeding of rice conferring resistance to planthoppers and leafhoppers

Jirapong Jairin[1], Masaya Matsumura[2], Hideshi Yasui[3]

[1]Kyushu University, Japan, [2]Kyushu Okinawa Agricultural Research Center, NARO, Japan, [3]Kyushu University, Japan

Insect pests are an important constraint in rice production in Asia. Among them, brown planthopper (BPH), Nilaparvata lugenes and green rice leafhopper (GRH), Nephotettix cincticeps are the most serious insect pests of rice in tropical and temperate Asia, respectively. Host-plant resistance is considered to be an economically, ecologically acceptable and practical approach for hoppers management. Several major resistance genes and quantitative trait loci associated with hoppers resistance have been identified in cultivated and wild relatives. Some of them have been transferred to desired genetic backgrounds to develop resistant varieties. Here we present some examples of identification of BPH and GRH resistance genes (i.e., BPH3, BPH4, BPH25, BPH26, GRH1, GRH2, GRH4, GRH5, and GRH6) and development of rice near-isogenic and pyramided lines with the resistance via marker-assisted selection. Through this approach, the resistance genes have been transferred to new genetic backgrounds and several unfavorable alleles linked to the target genes have been removed. The near-isogenic lines carrying the resistance genes should be useful to monitor the virulence of rice hoppers. The pyramided lines were significantly resistant to hoppers. This gene pyramiding strategy should be useful in rice breeding to develop broad-spectrum and durable resistant varieties.

Virulence monitoring and integrated management for main rice insect pests in South China

Fengkuan Huang[1], Suosheng Huang[2], Bi-qiu Wu[3]

[1]Guangxi Academy of Agricultural Sciences, China, [2]Guangxi Academy of Agricultural Sciences, China, [3]Guangxi Academy of Agricultural Sciences, China

This paper outlines recent research advances in virulence monitoring and integrated management for main rice insect pests in south China. Three components were discussed: (1) Monitoring the variation of the Virulences of main rice insect pests including brown planthopper Nilaparvata lugens (stal), whitebacked planthopper Sogatella furcifera (Horvath) and rice gall midge Orseolia oryzae Wood-Mason. (2) Evaluation and application of rice resistant germplasms and varieties to brown planthopper, whitebacked planthopper, rice gall midge. (3) Technologies and strategies of IPM for main rice insect pests in south China.Three key techniques were implemented: (a) resistant varieties, (b)cultural control and (c) judicious use of insecticides and protection of helpful insects and spiders.

Silicon-mediated rice resistance to the striped stem borer: Effects of rice varieties and larval stage

Yongqiang Han[1], Maolin Hou[2]

[1]*Chinese Academy of Agricultural Sciences, China,* [2]*Institute of Plant Protection, Chinese Academy of Agricultural Sciences, China*

The rice stem borer Chilo suppressalis is one of the most destructive pests in rice. The aim of this study was to investigate the potential of silicon addition in mediating rice plant resistance to first and third larval instars of C. suppressalis on a susceptible (Shanyou63) and a moderate resistant (Yanfeng47) rice variety. Potted rice plants were treated with calcium silicate at rates of 150 kg/ha (SiO2) or 600 kg/ha (SiO2) or left untreated (the control). Si amendment significantly increased Si content in rice stems, rice variety and interaction between Si treatment and rice variety also significantly influenced SiO2 content in rice stem. Percentage of larvae bored (PLB) decreased 5% or 28% with increases in Si addition. Percentage of larvae penetrated (PLP) did not differ among Si treatments or between rice varieties for the first instars; for the third instars, PLP significantly decreased 10% or 40% with increases in Si supply and was 10% to 30% lower on Yanfeng47 than on Shanyou63. Si addition significantly prolonged penetration duration (PD) in the first instars and in the third instars, PD was longer on Si+ Yanfeng47 than on Si+ Shanyou63. Analysis showed that increased SiO2 content in rice stems due to Si addition contributed to the reduction in PLP and prolong in PD of the third instar larvae. Silicon treatment significantly decreased larval development, weight gain and stem damage. Some of the effects were manifested more strongly in the susceptible rice cultivar compared with the moderate resistant cultivar.

Possible invasion areas of the alien apple snail, *Pomacea canaliculata*, estimated from accumulated climate data by automated meteorological data acquisition system (AMeDAS) in Japan

Takashi Wada[1], Keiichiro Matsukura[2]

[1]NARO Kyushu Okinawa Agricultural Research Center, Japan, [2]NARO Kyushu Okinawa Agricultural Research Center, Japan

The apple snail, Pomacea canaliculata, has become a major pest of rice in Japan, representing an important constraint on the implementation of direct seeding. Anticipating possible invasion areas is expected to prevent further spread. Cold weather is a major factor restricting its distribution in Japan. Mortalities increased depending on low temperatures below 10oC and exposure time. Therefore, we used cumulative low temperatures below 10oC during winter (CLT10) as an index to determine whether or not the snails can overwinter. Snail distributions were surveyed in several regions and CLT10 at each location calculated. The climate data at the specific locations was estimated from AMeDAS, using the software (Mesh2000). As a result the maximal CLT10 in which the snails can overwinter was estimated to be 700 day-degrees. We drew the areas below 700 day-degrees on a map as the possible invasion areas. The areas extended both regions of west Japan facing the Pacific Ocean and the Japan Sea. However, at present we found no snail distribution in the areas facing the Japan Sea except one location where hot-spring comes out. Furthermore, for the last 20 years snails in this place did not invade surrounding areas blow 700 day-degrees. Therefore we considered snow fall, another factor besides CLT10, which prevents overwintering, because temperatures are kept long at 0oC under snow. Thus, the areas where CLT10 are below 700 day-degrees together with the maximal snow fall being below 20 cm were drawn as the tentative map of possible areas invaded by P. canaliculata.

Integrated Pest Management

Looking back to move forward: Historical milestones of host plant resistance in integrated pest management succession

Sharron Sue Quisenberry
Iowa State University Ames, U.S.A.

Host plant resistance has long been part of crop protection with the first report of Hessian fly-resistant wheat cultivars in 1782, six years after the first report of a pest on wheat in the USA. The use of chemical insecticides proliferated worldwide during the 1940's through the 1960's because they were inexpensive and so effective that all other insect pest management tactics on crop plants, including host plant resistance, received little support. The overuse of insecticides resulted in outbreaks of insecticide-resistant insect pests, emergence of secondary pests to pest status, and the bioaccumulation of chlorinated hydrocarbon insecticides in the environment. This led to the re-examination of alternative tactics to chemical control and the concept of integrated pest management (IPM) as control strategy. In addition to host plant resistance to insects and diseases, substantial progress has been made using biological control tactics such as parasitoids, predators, and entomopathogens to manage insect pests. The introduction of transgenic crops (e.g., Bt-transgenic corn and cotton, etc.) has profoundly changed the concept of IPM. Interlinking the principles of genetics and ecology will profoundly impact our ability to protect crop yield and quality in the transgenic era.

Holistic corn breeding approach to improve abiotic and biotic and stress tolerance

Wenwei Xu
Texas A&M University, U.S.A.

Corn earworm, Helicoverpa zea (Boddie), is one of the major economic pests of corn both in the U.S. and worldwide. Its larvae feed on the corn silks and kernels, which increases grain mold by such fungi as Aspergillus flavus and enhances aflatoxin contamination in grain. Drought and heat stress reduces yield and increases aflatoxins. Our strategy to improve abiotic and biotic stress tolerance is to explore desirable native genes from exotic germplasm and wild species and develop multiple stress tolerance corn germplasm. The tropical x temperate breeding crosses from the Germplasm Enhancement of Maize (GEM) project are a useful source for selecting abitotic and biotic stress tolerant corn. Inbred CML343 and its hybrids are highly resistant to corn earworm. We have developed inbred lines from crosses between temperate x tropical corn or between corn x teosinte. Results showed that several experimental hybrids had high yield and significantly lower aflatoxins as compared to commercial hybrids. Improving host plant resistance to corn earworm and drought tolerance can be an effective approach to the risk of aflatoxin accumulation.

Genetic basis of wheat resistance to the English grain aphid

Huiyan Zhao[1], Zuqing Hu[2], Xiangshun Hu[3], Thomas Theime[4], Udo Heimbach[5], Gaisheng Zhang[6]

[1]Northwest A & F University, China, [2]Northwest A & F University, China, [3]Northwest A & F University, China, [4]Bio-test Laboratory, Germany, [5]Julius Kuhn-Institu (JKI), Germany, [6]Northwest A & F University, China

The English grain aphid is an important pest in wheat production worldwide. Development of aphid-resistant wheat and cereal varieties has been considered as one of the effective aphid management strategies in wheat and cereal production, which could reduce the use of synthetic insecticides, and improve crop yield and quality. A series of experiments were conducted to determine aphid resistance machenismms and understand the genetic basis for aphid resistance. After massive screening, 23 varieties were seleted from 2340 wheat germplasm as resistant to S. avenae. In particular, the varieties in XZ series, '98-10 ? 30 and '98-10 ? 35' were the best in aphid resistance among the selected wheat germplasm lines. Four linked SSR markers Xgwm350, Xbarc70, Xwmc702 and XCfd46 were identified, which were then used for aphid resistant gene mapping on 7DL chromosome in wheat. The distance of the four markers were 6.3 cM, 15.1 cM, 19.1 cM and 34.1cM on chromosome 7DL. Aphid resistant gene in wheat germplasm '98-10 ? 35' was determined on chromosome 7DL, which was designated as Sa1. Furthermore, aphid resistance in the F3 of 98-10-35/1376 was analyzed using DDRT-PCR technique. The banding patterns related to S. avenae resistance in the F3 plants could be categorized as the following five categories: 1) bands occurring in only parents; 2) bands occurring in only one parent; 3) bands visualized in only hybrid; 3) bands expressed in both hybrid and the resistant parent; 4) bands in the offspring being up-regulated; and 5) bands in the offspring being down-regulated.

Specific resistance of eight wheat varieties to *Sitobion avenae*, *Rhopalosiphum padi*, and *Schizaphis graminum* (Hemiptera: Aphididae)

Xiangshun Hu[1], Huiyan Zhao[2], Tongxian Liu[3]
[1]Northwest A. & F. University, China, [2]Northwest A. & F. University, China, [3]Northwest A. & F. University, China

Sitobion avenae, Rhopalosiphum padi and Schizaphis graminum were the three most destructive wheat pests worldwide. Many commonly used wheat varieties exhibited different resistance to different aphid species. We evaluated the resistance of eight varieties based on their negative (resistant), positive (susceptible), or no effects to the three aphid species using six parameters, development days, fecundity, weight difference between 1st instar and newly emerged adult, offspring per female produced per day, relative growth rates, and nymphal survival. We found that the effects of the eight varieties to the three aphid species differed significantly. The varieties, WW2730 and Astron were resistant to Sitobion avenae and R. padi, but susceptible to Schizaphis graminum; Batis was resistant to Schizaphis graminum, but susceptible to Sitobion avenae and R. padi; Amigo was only resistant to Schizaphis graminum; 98-10-30 was resistant to Sitobion avenae; Xiaoyan22 was resistant to R. padi, and had negative effects on the reproduction of Sitobion avenae and Schizaphis graminum, but had positive effects on the growth of Schizaphis graminum; 186tm was susceptible to all three aphid species, but caused the highest mortally to Schizaphis graminum and Sitobion avenae. The variety, 98-10-35 had negative effects on the reproduction of Sitobion avenae and development of R. padi, but caused the highest mortality to R. padi. We concluded that the wheat varieties have specific resistance to different aphid species. And the "trade-off" of host resistances exists on the wheat varieties level. Our data should be useful for aphid management and wheat breeding for aphid resistance.

Native host plant resistance to whiteflies in watermelon

Alvin Simmons[1], Amnon Levi[2]
[1]*USDA-ARS, U.S.A.*, [2]*USDA-ARS, U.S.A.*

Whiteflies (Hemiptera: Aleyrodidae), notably Bemisia tabaci (Gennadius), are destructive pests on a worldwide scale. B. tabaci feeds on over 1,000 host plant species with varying levels of infestations. This pest is a problem in cultivated watermelon [Citrullus lanatus var. lanatus (Thunbs) Matsum Nakai] because of its direct feeding and because it transmits viruses of important diseases. A series of studies were conducted for the development of native host plant resistance to whiteflies in cultivated watermelon. We have shown that a desert watermelon, Citrullus colocynthis (L.) Schrad, has resistance to whiteflies and to some other pests. Bioassays for native host plant resistance to whiteflies in C. colocynthesis accessions indicate that antibiosis, antixenosis and tolerance factors exert roles in the resistance. The bioassays identified differences among accessions within and among three selected species of Citrullus. Plant phenotype and leaf chemical profiles differ between accessions of C. colocynthis and watermelon cultivars. Moreover, plants of C. colocynthis accessions were noticeably odorous, and the total flavonoid content of their leaves was elevated as compared to watermelon cultivars. Genetic similarity and relationships were examined among accessions of Citrullus spp., Cucurbita maxima Duchesne (winter squash), Cucurbita pepo L. (squash and pumpkin), Cucumis melo L. (melon), Cucumis sativus L. (cucumber), and Lagenaria siceraria (Mol.) Standl (bottle gourd) showed that each is distinct with similar genetic distances among these species. Obtaining a good understanding of the genetics and mechanisms affecting native plant resistance of Citrullus is critical in the development of watermelon that is resistant to whiteflies.

Comprehensive field screenings for whorl- and ear-feeding insect resistance in corn germplasm lines

Xinzhi Ni
USDA-ARS Tifton, U.S.A.

A holistic approach to developing new corn germplasm that confers multiple insect resistance in various plant tissues at different growth stages was examined in two separate studies. The first study was the screening of eight corn germplasm lines for resistance whorl damage to fall armyworm [Spodoptera frugiperda (J. E. Smith) (Lepidoptera: Noctuidae)]. Four corn germplasm lines with known levels of resistance to root- and ear-feeding insects, and four germplasm entries with different levels of S. frugiperda resistance were evaluated in the study. Based on cluster analysis of S. frugiperda injury rating and predator survey data,'Mp708' and 'FAW7061' were the most resistant, whereas 'Ab24E' and 'EPM6' were the most susceptible to fall armyworm feeding. The western corn rootworm-resistant 'CRW3(S1)C6' showed resistance to S. frugiperda feeding. 'CRW3(S1)C6' and 'Ab24E' had the highest and lowest predator abundance, respectively. In the second study, 20 germplasm lines from the Germplasm Enhancement of Maize Program were examined. Four types of insect damage were assessed on corn ears. They were corn earworm [Helicoverpa zea (Boddie) (Lepidoptera: Noctuidae)] damage, maize weevil [Sitophilus zeamais Motschulsky (Coleoptera: Curculionidae)] -damaged kernels (%), stink bug-discolored kernels (%), and other chewing insect (e.g., sap beetles, chocolate milkworm, and pink scavenger caterpillar)-damaged kernels (%). Smut [Ustilago maydis (DC) Corda] infection rate, and husk tightness and extension were also assessed. Three of the 20 germplasm lines were identified as being multiple insect and smut resistant. Of the three lines, two were derived from 'DKXL370,' while the third line was derived from 'CUBA117.'

Constitutive and induced resistance to insects: Potential and limitations

Hari C. Sharma
International Crops Research Institute for the Semi-Arid Tropics, India

The physicochemical mechanisms of defense against herbivores are produced either constitutively and/or in response to plant damage. In addition, plants also release volatile compounds in response to herbivore damage that attract the natural enemies of the herbivores. Chemically induced expression systems or "gene switches" enable temporal, spatial, and quantitative control of genes introduced into plants or those that are already present in the plants to impart resistance to insect pests. A number of inducible genes have been identified in plants based on endogenous chemical signals such as phytohormones salicylic acid and jasmonic acid, response to insect and pathogen attack, or wounding. Effectiveness of the chemical injury inducers in providing resistance to various insect pests has also been demonstrated. Proteinase inhibitors and oxidative enzymes such as polyphenol oxidase, peroxidase, and lipoxygenase are active for 2 ? 3 weeks after induction in the damaged plants. Exogenous application jasmonic acid and salicylic acid has also been shown to induce resistance to several insect pests. Induced resistance, both in transgenic and non-transgenic plants offers a considerable promise to increase the levels of resistance to insect pests. However, the levels of constitutive and induced resistance quite often are not enough to exercise adequate control the target pests, and hence, HPR can be used in combination with other components of pest management to reduce pesticide use for sustainable crop production.

Repellent response of female agromyzid flies to leafminer-infested bean plants

Haihong Wang[1], Zhongren Lei[2], Xinzhi Ni[3]
[1]Chinese Academy of Agricultural Science, China, [2]Chinese Academy of Agricultural Science, China, [3]USDA-ARS, U.S.A.

Liriomyza sativae Blanchard, L. trifolii (Burgess) and L. huidobrensis (Blanchard) are three invasive leafminer species (Diptera: Agromyzidae) in China that have caused significant economic damage on vegetables and ornamental plants. In the current study, the repellent responses of female adults to leafminer-infested bean plants were examined with a Y-tube olfactometer. For both L. sativae and L. huidobrensis female adults, the repellent effect of the bean plants on which L. sativae had fed and oviposited was stronger than those on which L. huidobrensis had fed and oviposited. The repellent effect of the bean plants infested with L. sativae 2nd-instar larvae was stronger than those infested with L. huidobrensis 2nd-instar larvae. In a similar experiment using L. sativae and L. trifolii female adults, the repellent effect of the bean plants on which L. trifolii had fed and oviposited was stronger than those on which L. sativae had fed and oviposited. The repellent effect of the bean plants had infested with L. trifolii 2nd-instar larvae was stronger than those infested with L. sativae 2nd-instar larvae. The repellent effects of leafminer-infested bean plants on female adults was confirmed and is discussed in a context of ecological genetics of insect-plant interaction, interspecific competition and displacement of the leafmminers.

Impact of Scion and Rootstock Combination on Pest populations on Cherry and Apple Plants

Xin Li
Northwest A&F University, China

To determine the impact of grafting on insect pest populations on fruit trees, the combination of rootstock and scion cultivars on root and leaf pests was examined. The scarab beetle larvae (Scarabaeoidea) were used to assess for the effect on root pest population on cherry, while a leafminer (Lithocolletis ringoniella) (Lepidoptera: Gracilariidae) population was used for leaf pest assessment on apple plants. The results showed that mahaleb (Prunus mahaleb. C 500) as rootstock of two cherry cultivars [i.e., seven-year-old sweet cherry (Prunus avium) and sour cherry (Cerasus valgaris)] had significantly different number of scarab beetle larvae (23.1 ± 1.73, and 8.00 ± 0.73, respectively) (P = 0.0001). In contrast, when the leaf-feeding L. ringoniella on four apple cultivars with the same rootstock were compared, significant difference was detected in both leafminer population and its damage. The rootstock was Xinjiang wild apple (Malus sieversii) for four popular commercial apple cultivars 'Gala,' 'Fuji,' 'Qinguan,' and 'Hongxin,' respectively. The number of L. ringoniella larvae was significantly (P = 0.0001) different among the four cultivars. Qinguan had the most [(59.10 ± 2.68) / 100 leaves], whereas Red Star had the least number of the larvae [(25.00 ± 1.98) / 100 leaves]. The most severe leaf damage by L. ringoniella was on Gala (10.01 ± 1.49%), the least damage was on Hongxin (1.56 ± 0.60%). Thus,optimized selection of rootstocks and scions with native insect resistance could be one of the effective tactics for the integrated pest management in fruit crop orchards.

Resistance in Peach Rootstocks and Scions to Lesser Peachtree borer (Synanthedon pictipes, Lepidoptera: Sesiidae).

Ted Eric Cottrell[1], Tom Beckman[2], Dan Horton[3]
[1]USDA, U.S.A., [2]USDA, U.S.A., [3]University of Georgia, U.S.A.

The lesser peachtree borer, Synanthedon pictipes (Lepidoptera: Sesiidae), is of economic concern to peach, Prunus persica (L.) Batsch, production across the southeastern United States. Oviposition by S. pictipes was examined on field-grown Prunus scion and rootstock cultivars and two endemic Prunus spp. using limbs, not roots, in the laboratory. In this study, oviposition was compared on the peach scion `Harvester', peach rootstock `Guardian', plum × peach hybrid rootstock `MP-29', and the plum hybrid rootstock `Sharpe'. A significantly lower percentage of eggs occurred on limbs of Sharpe rootstock than other choices. A choice test using two endemic hosts, black cherry (P. serotina) and Chickasaw plum (P. angustifolia), along with Sharpe rootstock, found a lower percentage of eggs on limbs of Sharpe than either endemic host. Earlier research found these two endemic hosts of S. pictipes less preferable for oviposition than peach cultivars. However, when only limbs of Sharpe and a decoy were used, almost all eggs were laid on Sharpe. But when Harvester and Sharpe limbs were paired side by side, a higher percentage of eggs were found on the Harvester limb than on the Sharpe limb. Because S. pictipes attacks host trees above ground and Sharpe rootstock on grafted trees grows below ground, this rootstock might be a management option against the congeneric, root-attacking peachtree borer, S. exitiosa (Say).

Patterns of Host Adaptation in *Frankliniella occidentalis* among Vegetable Crops

Zhongren Lei[1], Haihong Wang[2], Xinzhi Ni[3]

[1]Chinese Academy Agricultural Sciencies, China, [2]Chinese Academy Agricultural Sciencies, China, [3]USDA-ARS, U.S.A.

The current study examined the variation in life table characteristics, and physiological, biochemical, and molecular bases of western flower thrips , Frankliniella occidentalis (Pergande) host adaptation patterns. The main objective was to determine whether host availability affects insect preference or population diversion on different hosts throughout the field season of vegetable crop production. Three vegetable hosts were used in the study. They were bean, garlic and pepper. Host shift made F. occidentalis offspring displayed longer developmental time, lower survival rate, lower oviposition rate, especially at the F1 generation, but the reduction recovered in the following generations. Host-returning test showed that F. occidentalis biological characteristic recovered a little, but it still has significant difference with original host population and adaptive host population. hybridization made F. occidentalis populations between different hosts showed that, host preference and other biological characteristics were never as strong as its parental populations. Detoxification enzyme activity bioassays showed F. occidentalis could activate its detoxification enzymes to cope the allelochemicals in the new host, especially at the initial stage of host change test. The detoxification enzyme activity was the highest within 24 h. After six generations, the detoxification enzyme activity was relatively stabilized, but it was still higher than the thrips fed on the control. When the differentiation among 5 populations was examined using RAPD technique, the study revealed there was a significant differentiation in these host-specific populations. The ramifications of host shift of pests in integrated pest management on vegetable crops are also discussed.

Variation of cross-resistance of Cry1Ab- and Cry1Ac-selected Asian corn borer to other Cry toxins

Mingxia He[1], Xu Yang[2], Ning Li[3], Zhenying Wang[4], Qunfang Yang[5], Kanglai He[6]

[1]Sichuan Agricultural University, China, [2]Institute of Plant Protection, CAAS, 2 Sichuan Agricultural University, China, [3]Chinese Academy of Agricultural Sciences, China, [4]Chinese Academy of Agricultural Sciences, China, [5]Sichuan Agricultural University, China, [6]Institute of Plant Protection, Chinese Academy of Agricultural Sciences, China

One of many strategies proposed to delay pest resistance to Bt crops is multi-genes strategy which could be practiced through multiple toxins in sequence use and/or different crops as well as pyramiding of more than one toxin. However, one requirement for the multi-genes strategy to work is that those different toxins should be not affected by cross-resistance. Understanding the cross-resistance patters of Ostrinia furnacalis with resistance to cry toxins from Bacillus thuringensis is key to developing multi-genes strategy for delaying resistance to Bt maize. The susceptibility of F1 offspring of reciprocal crosses between Cry1Ab- and Cry1Ac-resistant strains (ACB-AbR and ACB-AcR) to Cry1Ab, Cry1Ac, Cry1F, and Cry1Ie toxins were evaluated. Resistance levels exceeded 35- and 74-fold at 50% lethal concentration of the ACB-AbR and ACB-AcR strains, respectively. In addition, it was significantly decreased in susceptibility to Cry1Ac and Cry1IF in ACB-AbR strain with cross-resistance levels of 61- and 18-fold. Meanwhile, it was decreased in susceptibility to Cry1Ab and Cry1IF in ACB-AcR strain with cross-resistance levels of 10- and 16-fold. Allelic complementation tests were complementary and suggested that ACB-AbR and ACB-AcR evolved resistance to Cry1Ab, Cry1Ac, and Cry1F at common loci. The patterns of cross-resistance suggest Cry1Ac share same binding sites with Cry1Ab, and Cry1F shares one or more receptor with Cry1Ab and Cry1Ac. In contrast, ACB-AbR and ACB-AcR as well as the offspring of their reciprocal crosses were equally susceptible to Cry1Ie suggested that Cry1Ie did not share binding sites with Cry1Ab and Cry1Ac on BBMV of Asian corn borer.

Area-wide monitoring of resistance to *Bacillus thuringiensis* Cry1Ab maize in *Diatraea saccharalis*

Fangneng Huang[1], Mukti N Ghimire[2], B Rogers Leonard[3], Chris Daves[4], Ronnie Levy[5]

[1]Louisiana State University Agricultural Center, U.S.A., [2]Louisiana State University Agricultural Center, U.S.A., [3]Louisiana State University Agricultural Center, U.S.A., [4]Mississippi State University, U.S.A., [5]Louisiana State University Agricultural Center, U.S.A.

The sugarcane borer, Diatraea saccharalis (F.), is a major target of transgenic maize expressing Bacillus thuringiensis (Bt) proteins in South America and the mid-southern region of the United States. During 2004-2009, a total of 3107 feral individuals of D. saccharalis were collected from multiple locations in Louisiana, Texas, and Mississippi and examined for resistance to Cry1Ab maize using F1/F2 screens. Major resistance alleles to Cry1Ab maize in the populations sampled during 2004 and 2008 in Louisiana, and 2007 in Texas, and 2009 in Mississippi were rare. The frequency of major resistance alleles was estimated to be 0.0011 with a 95% CI of 0.0003-0.0024 for the Louisiana populations sampled from 2004-2008, <0.0016, with 95% probability, for the Texas populations, and <0.0061 for the Mississippi populations. However, resistance allele frequency for the populations sampled in 2009 in Louisiana increased significantly, reached 0.018 with a 95% CI of 0.008 to 0.03. Since 2010, transgenic maize expressing pyramided Bt genes has been planted in the U.S. mid-southern region and by 2011, pyramided Bt maize already replaced the Cry1Ab maize as the dominant Bt maize traits for managing lepidopteran pests including D. saccharalis. The timely switching of the single-gene Cry1Ab maize to the pyramided Bt maize should prevent further increase of Cry1Ab resistance allele frequency and thus ensure the continued success of Bt maize for managing D. saccharalis in the region.

Moving forward: Trends and future prospects of biotechnology in transgenic crops for insect control

Jeng Shong Chen
Syngenta Biotechnology, Inc., U.S.A.

Biotechnological innovations in transgenic insecticidal crops has commenced a new era of crop yield protection. This technology is well embraced by farmers because it is affordable, safe, convenient and highly efficacious. However, it still faces problems such as development of resistant populations, and shift of target pest insects. A successful IRM program requires multiple modes of action to effectively mitigate the risk of development of resistance. Availability of genes with new insecticidal spectrum is a key to combat outbreaks of newly emerged pest insects in time. With issues of negative phenotypes, not every insecticidal gene can be successfully expressed in crop plants and developed into a product. To date, Bacillus thuringiensis is still the only source of commercialized insect control trait genes. Several genes with insecticidal activities were discovered from those so-called non-Bt species. Yet, most of them encountered major expression obstacles in planta. None has been commercialized thus far. Recently there has been a rapid increase of products containing stacked traits generated by conventional breeding of different trait events, or by molecular stacking of multiple traits in a single transgene locus. Such a trend continues to push the limits of biotechnology, seed production logistics and product registration.

Integrated Pest Management

Evaluating the IPM fit of insecticides ? Sorting myth from reality

Lewis Wilson[1], Simone Heimoana[2]
[1]CSIRO, Australia, [2]CSIRO, Australia

Establishing the 'fit' of insecticides in IPM is crucial to optimise their use and maintain beneficial populations in the crop and landscape. To provide timely information to pest management practitioners we developed a simple approach that allows the IPM fit of insecticides to be evaluated and compared. Field plots of cotton are established in a replicated design. Sunflowers are planted between replicates to help reduce pesticide drift risks and provide a source of pests and beneficials. A range of new or candidate insecticides are applied 4 to 5 times at 10 d intervals and plots sampled for pests and beneficials pre-spray and twice between applications. Sampling includes; suction sampling for mobile arthropods, leaf washing for sedentary arthropods and visual checks for arthropods not well sampled by the former techniques. Data are analysed for treatment effects, and insecticides ranked according to the reduction in beneficial abundance, for each species or group, compared with the untreated control; VL (very low), less than 10%; L (low), 10-20%; M (moderate), 20-40%; H (high), 40-60%; VH (very high), > 60% and the risk of pest resurgence. Outcomes are then summarised in an easy-to-use look-up chart which is distributed to all pest managers and cotton growers. Meta-analysis of commercial crops managed with more selective insecticides showed they had higher beneficial populations, confirming the value of rankings generated using this method. Though there are many trade-offs with such an approach it has been valuable in increasing adoption of IPM principles in cotton.

Fungal endophytes as insect management tools in cotton

Gregory A. Sword[1], Maria Julissa Ek-Ramos[2], Diana Castillo Lopez[3], Wenqing Zhou[4], Cesar Valencia[5]
[1]Texas A&M University, U.S.A., [2]Texas A&M University, U.S.A., [3]Texas A&M University, U.S.A., [4]Texas A&M University, U.S.A., [5]Texas A&M University, U.S.A.

Plants commonly harbour a diversity of fungi as asymptomatic endophytes that can provide protection from a range of biotic and abiotic stressors. In order to better characterize the diversity and potential functions of fungal endophytes associated with cotton (Gossypium hirsutum), we surveyed the diversity of fungal endophytes in cultivated cotton across multiple sites in Texas, USA. We recovered a number of fungal endophytes that are known to act as antagonists against insects, plant pathogens, and nematode pests. In greenhouse trials to investigate effects on insect herbivores, we successfully inoculated cotton seedlings using seed treatments of a field-collected endophytic strain of Paecilomyces sp. and a commercially available strain of Beauveria bassiana. In both cases, cotton aphid (Aphis gossypii) reproduction was significantly reduced on endophytically-colonized plants versus uninoculated controls in greenhouse performance assays. An important consideration for the potential use of fungal endophytes in IPM is the potential for either positively or negatively correlated effects of endophytic colonization on plant performance. We found varying dose-dependent effects of both B. bassiana and Paecilomyces sp. endophytic colonization on total plant biomass, shoot and root length of endophyte-colonized versus uninoculated control cotton seedlings. Results of ongoing replicated field trials testing endophyte inoculation efficiency and protection from insect herbivores will be discussed.

Integrated Pest Management S1010

Integrating natural enemies and semiochemicals in cultural control for an effective IPM

Stefano Colazza[1], Ezio Peri[2], Antonino Cusumano[3]

[1]university of palermo, Italy, [2]university of palermo, Italy, [3]university of palermo, Italy

Since their discovery, many semiochemicals (behavior modifying chemicals) have been identified and synthetized, and a number of techniques have been developed to use them in integrated pest management (IPM) programs against insect pests. In particular, the uses of semiochemicals in IPM to monitor insect pest populations and to interfere with their behavior preventing agricultural damage are widely adopted by the growers. In the same time, evidences that semiochemicals can also modify the behavior of insect natural enemies inspired researchers to explore the possibility to use semiochemicals to conserve and/or enhance the efficacy of natural enemies in cropping systems. However the use of semiochemicals integrated with natural enemies in IPM is still limited despite the fact that scientists have made important advances in recent years to elucidate semiochemical-natural enemies interactions in multitrophic contexts. Here we provide an overview of the IPM strategies integrating semiochemicals and natural enemies; furthermore, the factors that could be considered for more widely adoption of these strategies are discussed.

Dispersal of *Euschistus servus* (Heteroptera: Pentatomidae) in time and space

Michael Dennis Toews[1], John Herbert[2], Ta-I Huang[3], Ishakh Pulakkatu thodi[4]

[1]University of Georgia, U.S.A., [2]University of Georgia, U.S.A., [3]University of Georgia, U.S.A., [4]University of Georgia, U.S.A.

Phytophagous stink bugs are one of the key agricultural pests of food and fiber production around the world. In the southeastern United States, Euschistus servus is one of the most common stink bug species found feeding on cereal grains, row crops, tree fruits, and vegetables. Studies were conducted to investigate population dynamics, population structure, and intercrop movement by E. servus in agricultural farmscapes. Research methods included weekly sweep net sampling, mark and capture, and dissection of adults to rate gonad development. Data show that this species is clearly bivoltine and utilizes a wide range of nonagronomic and agronomic hosts over the course of a single year. Adults overwinter from November through February before emerging and completing a generation on naturally occurring plants or winter wheat. First generation adults invade corn, peanut, cotton and eventually late season soybean where they oviposit resulting in the second generation that completes development in early October. Adults invade cotton starting when the plants began to bloom and continue moving into cotton through the bloom period. Intercrop flight distance was generally short (2.7 to 8.2 meters in 24 h), but was highly aggregated on the edges of fields. Results show that there are predictable patterns in population growth and dispersal into fields.

Landscape-level cultural control as an arthropod pest management approach in Texas High Plains cotton agroecosystems

Megha N. Parajulee[1], Ram B. Shrestha[2], William O. McSpadden[3], Stanley C. Carroll[4]

[1]Texas A&M University System AgriLife Research, U.S.A., [2]Texas A&M University System AgriLife Research, U.S.A., [3]Texas A&M University System AgriLife Research, U.S.A., [4]Texas A&M University System AgriLife Research, U.S.A.

A comprehensive cultural management study, integrating landscape characteristics potentially influencing crop and non-crop source-sink relationships, characterized Lygus hesperus seasonal population dynamics in the Texas High Plains. Supporting sinks and destroying refuges adjacent to the crop are effective for managing some arthropod pests. However, determining the propensity of host source or sink is challenging, especially for highly mobile and polyphagous pests such as Lygus hesperus. A four-year project involved surveying and sampling Lygus in several sub-regions of the southwestern United States, including the Texas High Plains. In Texas, geographic information of the landscape vegetation complex was compiled from a 150-km radius region. Fifty irrigated cotton fields, selected to represent regional cotton diversity, and up to six non-cotton insect habitats within a 3-km radius of each, were sampled via sweep-net for 10 weeks. Seasonal average Lygus abundance data were regressed with 27 field characteristics (variables). These included habitat land coverage, distance between cotton and non-cotton habitats, habitat heterogeneity index, and numerous environmental/ecological variables. A 10-parameter linear model explained 93% of data variation. Parameters contributing significantly to variation in Lygus abundance in cotton were corn and sunflower acreages, cotton distances from several non-cotton hosts, and habitat heterogeneity index. Field marking and capture (FMC) studies were conducted using protein markers and enzyme-linked immunosorbent assays to characterize Lygus intercrop movement behavior. FMC can be used to study the effects of various crop management practices on L. hesperus intercrop movement and may apply to other pests and cropping systems.

Spatio-temporal dynamics of mirid bug *Creontiades biseratence* (Distant) in Bt cotton and other host crops: An intraguild assessment in the endemic area of an emerging pest

Shashikang Shiddappa Udikeri[1], Manohar Veerappa Shyadaguppi[2]
[1]*University of Agricultural Sciences, India,* [2]*University of Agricultural Sciences, India*

From 2002 commercially Bt cotton cultivation started in India making it largest grower (110 lakh ha) in the world. The ruling events have Cry 1 Ac as single or stacked gene. The reduction of insecticides on Bt-cotton is presumed to have led to an enhanced infestation of mirid bugs, mealy bugs. Like in Australia, China and US mirid bugs are becoming key pests in India also with advent of Bt cottons. Since 2005 mirid bug, Creontiades biseratence (Distant) (Hemiptara : Miridae) has emerged as major sucking pest in South India particularly in Karnataka state. Its most aggressive impact is being experienced in Haveri. Acephate and Profenophos are chemical control options. In present study the seasonlong dynamics of mirid bug in Bt cotton as well as its alternate hosts has been studied across 13 locations in Haveri district to address an endemic area intraguild. The peak incidence of mirid bugs (390/100 squares) was in second fortnight of November though it could exists throughout season. Summer cultivation of cotton also had severe infestation offering a niche is main-season off period. The mean incidencein the district was 128.3±18.3 / 100 squares. The incidence was in severe form throughout district on cotton. The key alternate host crops were pigeonpea, sunflower, sorghum, safflower, maize, castor and amaranthus. Maximum incidence of mirids was on pigeonpea (14.0±3.5 bugs/pl) and on maize. The correlation was significant, positive (r= 0.78) between pigeonpea and cotton mirid incidence. Sunflower was related negatively (r= -0.44).In an intraguild pigeonpea and maize could

Area-wide pest management of sucking bugs in temperate climates benefits from a landscape perspective in managing vegetation: Lessons from field crops of the North American Great Plains

Michael J. Brewer[1], Norman C. Elliott[2], Megha N. Parajulee[3]

[1]Texas AgriLife Research, U.S.A., [2]USDA ARS Plant Science Research Laboratory Stillwater, U.S.A., [3]Texas A&M University AgriLife Research, U.S.A.

Pest management in field crops may best be approached from an area-wide perspective because of low crop value and spatially-variable pest severity. This situation provides the opportunity (and the challenge) to consider: a) regional pest risk assessment, and b) pest management tactics applied regionally. In the North American Great Plains, area-wide strategies are based on host plant resistance, crop diversification, and association of crops with non-crop host plants. Producers use aphid-resistant wheat cultivars when available and apply this tactic regionally where aphids regularly occur. Application of crop diversification occurs less frequently on wheat, unless it is linked to water conservation. In cotton growing regions of the southern plains, a complex of sucking bugs occurs. Key species have known sensitivity to cotton spatially associated to varying degrees with weeds, neighboring crops, and other landscape features. Regional pest risk assessment can be derived from analysis of these associations. Across these examples, plant diversification (habitat heterogeneity) measurement is useful for regional pest risk assessment, but its active manipulation is often contingent on non-pest issues. In contrast, host plant resistance has a rich history in area-wide aphid control.

Integrated Pest Management

The contribution of IPM to food security in the developing world

Christian Wilheim Borgemeister[1], Aziz Ajlan[2]

[1]International Centre of Insect Physiology and Ecology, Kenya, [2]King Faisal University, Saudi Arabia

The recent spike in food prizes worldwide and resulting civil unrest and riots in many developing countries have been a strong reminder of the growing problem of food insecurity in many countries of the world. Several factors like growing populations in the south, stagnant yields of many important agricultural crops, increasing competition between agricultural and biofuel production for arable land, and the increasingly detrimental effects of global climate change on agricultural productivity, especially in the developing world, sparked some serious rethinking on the future of agriculture. Initially the emphasis was mainly on increasing agricultural productivity through improvement of germplasm and intensification, e.g. through mineral and organic fertilization. However, there are serious pitfalls of such a strategy, particularly with regard to the resilience and sustainability of such intense production systems. An alternative but also complementary approach is looking at loss prevention and loss reduction. Biotic constraints like pests and diseases are among the most important yield-limiting factors for agriculture worldwide, and particularly in tropical and subtropical environments. Approximately 30-40% of the potential agricultural pre- and post-harvest output in the developing world is lost to pest and diseases. In this symposium we are trying to establish if and how Integrated Pest Management (IPM) can contribute to alleviate food insecurity in the developing world.

Advance in integrated pest management of crops in China

Kongming Wu
Institute of Plant Protection, China

Integrated pest management (IPM) in crops is an important strategy for insect pest control, which plays important role for sustainable agriculture. In order to meet demand of crop production in China, Chinese government launches a series of scientific program for insect pest researches in recent years. In follow of these projects, China has established a national and province network which consists of scientist teams and special facilities for insect pest researches in universities and institutes. And many achievements on pest control such as methods and technologies on monitoring and forecasting for outbreaks of major pest insects, ecological management for insect population, biological control, chemical control, and the commercial use of transgenic insect-resistant crops, as well as IPM systems in cotton, rice, corn, wheat, vegetables and other crops, have been established in recent years. The rapid progress from modern sciences such as biological engineering and information technology is bring a new revolution for agriculture science, which is pushing IPM theory forward and giving a new opportunity for IPM application in China. Deployment of GPS, GIS and computer science in pest management is taking pest monitoring and forecast work to a high level. Commercialization of insect resistance genetically modified crops is presenting a great potential for regional control of insect pests. Researches on landscape biodiversity and conservation biological control provide an important idea for developing sustainable agriculture in China.

Field evaluation of trap capture based threshold for application of entomopathogenic fungi in management of thrips on French beans

Alexander Mutua Muvea[1], Subramanian Sevgan[2], Hellen Kutima[3], Zipporah Osiemo[4], Monicah Waiganjo[5], Willem J De Kogel[6]
[1]Jomo Kenyatta University of Agriculture and Technology, Kenya, [2]International Centre of Insect Physiology and Ecology, Kenya, [3]Jomo Kenyatta University of Agriculture and Technology, Kenya, [4]Jomo Kenyatta University of Agriculture and Technology, Kenya, [5]Kenya Agricultural Research Institute, Kenya, [6]Plant Research International B.V., Netherlands

French beans (Phaseolus vulgaris L.) are an important high value crop in Kenya. Straightness and spotlessness are important quality attributes of French beans. Thrips infestation on French bean leads to spotting and malformations making them unsuitable for the market. Kenyan growers rely heavily on chemical insecticides for thrips control without consideration of the side effects and control costs. Thus, finding alternative control options based on timely intervention is important to minimize negative effects of chemical sprays. Studies were conducted over two cropping periods to evaluate trap capture based economic threshold for application of Metarhizium anisopliae (Metsch) for management of thrips on French beans. The application of M. anisopliae at thresholds of 300, 600 and 900 thrips per trap per week effectively reduced the thrips population as compared to untreated control. The number of sprays of M. anisopliae decreased with an increase in the threshold level. Control plots and plots treated with alpha cypermethrin had the highest population of F. occidentalis as compared to the fungus treatments. Highest yield of French bean resulted from fungus application at 300 thrips per trap per week and it was comparable to yields from weekly sprays of M. anisopliae and alpha cypermethrin. Thus fungus based thrips management at action threshold of 300 thrips/trap/week reduced thrips incidence, increased yield, reduced number of sprays upto 20% and resulted in the highest net income.

Integrated Pest Management

Development and diffusion of a new IPM approach for potato in the Andean region of Peru

Jurgen Kroschel
International Potato Center (CIP), Peru

Many insect pests have co-evolved with potato in the center of origin in the Andes of Peru. Farmers control infestations of Andean potato weevils (Premnotrypes suturicallus) by applying hazardous insecticides. While weevils are the major pest above 3800 m asl, in inner Andean valleys also occur potato tuber moths (Phthorimaea operculella, Symmetrischema tangolias) and occasionally flea beetles (Epitrix spp.). We developed IPM that consists of new technologies and strategies (i) to inhibit the migration of weevils by using plastic barriers; (ii) to scout the occurrence of flea beetles and eventually control by one single application of low-toxic insecticides, and (iii) to apply attract-and-kill to manage potato tuber moths. A talcum-B. thuringiensis (Btk) product and attract-and-kill are highly effective for IPM in potato stores. Further, we consider the recuperation of parasitoids, lost through the intensive use of pesticides. The new technologies are well perceived by agricultural extension workers and farmers. Organic growers, in particular, have shown immediate interest in adopting plastic barriers. Partnerships have been built up with the private sector to introduce and make available plastic in adequate sizes (40 cm wide) and quality, and to register and commercialize a low-cost biocontrol product based on Btk as well as attract-and-kill (AdiosMacho). Main limiting factor for implementing IPM is the heavy competition of agrochemicals to which farmers have easy access through a strong network of pesticide sellers. The role of the Peruvian government is important for the regulation of highly toxic pesticides and for the wider promotion of IPM.

Some factors affecting the productivity of maize in small scale farmers' fields in Ekpoma, Edo State, Nigeria

Nathaniel Osawe Oigiangbe[1], Benjamin Igho Igbinosa[2], Manuele Tamo[3], Mark Edewede[4], Osagie Izebhijie[5]

[1]Ambrose Alli University, Nigeria, [2]Ambrose Alli University, Nigeria, [3]International Institute of Tropical Agriculture, Benin, [4]Ambrose Alli University, Nigeria, [5]Ambrose Alli University, Nigeria

Some factors affecting the productivity of maize, Zea mays L., were investigated in resource poor farmers' fields in Ekpoma, Edo State, Nigeria, during the 2011 first and second planting seasons. Maize stand loss was more severe (42.83% t0 60.34%) between 11 and 13 weeks after emergence (WAE). Damage by stem borers was very low until 11 WAE (14.35%) and reduced to 4.43% at 13 WAE. Termites' damage increased from 35.44% to 56.96% (2 to 4 WAE) and decreased sharply, 16.24% to 0.00% (5 to 13 WAE). Defoliation was highest (49.58% to 80.38%) at 2 to 5 WAE, but wilting was more severe (15.40% to 28.69%) at 9 to 13 WAE. Significant positive correlations were found between the number of stands and defoliation ($r = 0.7544$; $P < 0.0001$) as well as dmage by termites ($r = 0.5108$; $P < 0.01$). Damage by stem borers was not significantly different between the seasons, but cob tip damage by earworms was significantly higher during the first season (0.84%), compared with the second season (0.30%). There was a significant negative correlation ($r = -0.4519$; $P < 0.01$) between the length of the sheath of the flag leaf and damage to the tip of the cob. The weight and length of the cobs had significant positive correlations with the length of the flag leaf and the entire maize stalk. The implications of these results in the development of effective insect pest management strategies to improve maize production among resource poor farmers are discussed.

Integrated Pest Management

How the use of integrated pest management for vegetables contributes to food and nutritional security in Asia

Srinivasan Ramasamy
AVRDC-The World Vegetable Center, Taiwan

Approximately 85% of global vegetable production occurs in Asia, on about 78% of global vegetable area. Pests and diseases constrain vegetable production in tropical Asia and growers rely heavily on chemical pesticides for control. Pesticide application often exceeds 50 sprays per crop season on eggplant in the Philippines or tomato in south India. Indiscriminate use of pesticides leads to the development of resistance in major insect pests including tomato fruitworm (Helicoverpa armigera), eggplant fruit and shoot borer (Leucinodes orbonalis), diamondback moth (Plutella xylostella), and whitefly (Bemisia tabaci). Overuse of pesticides degrades the environment and causes resurgence of secondary pests. Alternative integrated pest management (IPM) strategies are warranted to reduce pesticide residue on vegetables and in the environment, and to protect human health. For four decades, AVRDC ? The World Vegetable Center has developed and promoted effective vegetable IPM strategies to manage insect pests on brassicas, eggplant, vegetable legumes and tomato in tropical Asia. These strategies have decreased pesticide misuse and enhanced the income and livelihoods of people throughout the region. With the introduction of biological control of P. xylostella in Southeast Asia, the income of growers doubled due to reduction in spraying costs and increased productivity. In South Asia, eggplant IPM adopters increased their profit margins and their crop acreage. The per capita availability of vegetables has almost doubled in Asia over the last two decades, in part due to IPM; people now have greater scope to improve their diets with a variety of nutritious and health-promoting vegetables.

Integrated Pest Management

Push-Pull: A platform technology for enhancing food security and environmental sustainability in Africa

Zeyaur Khan[1], Charles Midega[2], Jimmy Pittchar[3], Toby Bruce[4], John Pickett[5]

[1]International Centre of Insect Physiology and Ecology (icipe), Kenya, [2]International Centre of Insect Physiology and Ecology (icipe), Kenya, [3]International Centre of Insect Physiology and Ecology (icipe), Kenya, [4]Rothamsted Research, United Kingdom, [5]Rothamsted Research, United Kingdom

The Push-Pull technology is based on a novel cropping system developed for integrated pest, weed and soil management in cereal-livestock farming systems. The system makes use of two kinds of companion plants, a trap crop that serves as an attractant for stem borers, to pull them away from cereal field, and a second crop intercropped within the rows of cereal crop to repel the pests. The most effective trap crop, Napier grass, is planted as a border around the main crop. The fodder legumes in the genus Desmodium act as a repellents for stemborers with the added benefit of fixing nitrogen in the soils as well as serving as a cover crop to prevent soil erosion. The root exudates of Desmodium spp. contain novel flavonoid and isoflavonoid compounds that interfere with striga parasitisation of cereals. Both Napier grass and Desmodium plants provide high value animal fodder, facilitating milk production and diversifying farmers' income sources. The technology is appropriate to smallholder farmers practicing mixed cropping systems in Africa. It effectively addresses major production constraints, and increases cereal yields (eg, maize yields from below 1 to 3.5t/ha). The technology is economical as it is based on locally available plants and not expensive external inputs. Adopted by over 47,000 farmers to date in East Africa, key factors in its further up-scaling include effective technology dissemination, adaptability of companion plants for climate resilience, capacity building, multi-stakeholder collaboration, integration with livestock husbandry, improvement in Desmodium seed accessibility and creation of a supportive policy framework.

Integrated Pest Management

Success and challenges in integrated management of cassava and plantain pests in sub-Saharan Africa

Rachid Hanna[1], Lava Kumar[2], James Legg[3], Apollin Fotso Kuate[4], Sergine Ngatat[5], Armand Doumtsop[6]

[1]International Institute of Tropical Agriculture (IITA), Cameroon, [2]IITA, Nigeria, [3]IITA, Tanzania, [4]IITA, Cameroon, [5]IITA, Cameroon, [6]IITA, Cameroon

Pests and diseases continue to be the main constraints of cassava and plantains, two major staple crops in sub-Saharan Africa. Biological control has been successful against exotic pests - cassava green mite and cassava mealybug, but not against indigenous pests ? the whitefly Bemisia tabaci and the scale Stictococcus vayssierei. Similarly, the main plantain pests, the weevil Cosompoletis sordidus and the aphid Pentalonia nigronervosa - vector of banana bunchy top virus have required complicated integrated solutions. A combination of biological control and host plant resistance are presently being explored for the management of Bemisia tabaci. For the management of S. vayssierei, a combination of tolerant cassava genotypes, ant control and pre-planting host residue removal have been developed, but the implementation of these options ? other than tolerant varieties ? continue to be quite challenging. Cosmopoletis sordidus has received a great deal of research which has resulted in the development of integrated options using host plant tolerance, biological and microbial control (including endophytes) and cultural management. Although successful in weevil suppression, these have not been widely implemented and adopted. Recent research on the duo of the aphid P. nigronervosa and banana bunchy top disease (BBTD) has not identified any effective natural enemies of the aphid but limited success has been achieved in identifying plantain genotypes with reduced susceptibility to the aphid and BBTD, which are now being explored in combination of sanitation options in the management of banana aphid and BBTD.

IPM in date palms and its contribution to food security in the Middle East

Aziz M Ajlan
King Faisal University, Saudi Arabia

The date palm, Phoenix dactylifera, is considered one of the oldest fruit trees, which is mentioned in the Qur'an and Bible. There are 100 million date palms worldwide, of which 62 million palms can be found in the Middle East, which are the major countries to produce dates that are most used by Middle East people as food security. Currently, 26 palm species are reported as hosts of the red palm weevil (RPW), Rhynchophorus ferrugineus. In the mid-1980's, it entered in the date plantations of the arid Middle-Eastern region from where it moved into Africa (Egypt) in the early 1990's and subsequently into Europe (Spain). It is devastating Phoenix canariensis in the Mediterranean basin. In 2009, it gained entry into the Caribbean (Curacao Island). In 2010, it was detected into Lebanon and Laguna Beach, California and in Dec. 2011 in Carthage, Tunisia. RPW mostly infests young palms less than 20 years old with a single female laying about 300 eggs in its lifespan. Palms in the early stage of attack are difficult to detect while infested palms in the late stage of attack harbor several overlapping generations that exhibit extensive tissue damage. Such severely infested palms do not respond to curative treatment and have to be eradicated. RPW is currently managed through a pheromone based Integrated Pest Management (IPM) strategy where early detection of infestation is the key to ensure success. Implementing of quarantine regulations is essential to curtail the spread of this pest.

Integrated Pest Management

IPM in rice - Has it contributed to food security in Asia?

K. L. Heong
International Rice Research Institute, Philippines

Rice IPM became prominent in 1986 when Indonesia announced a ban of 56 insecticides, removed the subsidy and introduced IPM field schools. Since then millions have been spent and about a million farmers have "graduated" from IPM-FFS. This was instituted when Indonesia and many Asian countries were experiencing massive destructions by the brown planthopper (BPH). Thirty years later, rice production in Asia is experiencing far greater and persistent threats from the BPH and virus diseases than ever before. Thailand is losing rice to BPH for 9 consecutive seasons. In 2010 Thailand rice production lost 1.1 million tons of paddy and in 2012, a loss of 500,000 tons is expected.. Similarly Indonesia is suffering the same threats and had lost about a million tons. BPH is an insecticide induced secondary pest and outbreaks are due to mismanagement that destroys ecosystem services. We now need to ask the hard questions "Has IPM really contributed to rice food security?". If IPM had been successful, why is it that we now face the same problem that IPM was meant to fix? Why does this problem continue to haunt and threaten rice production in Asia? The presentation looks at the current state of insect management in rice, BPH outbreak threats, factors that might have contributed to eroding the gains from IPM and explores for a broader framework for improvements. It will discuss structural and policy issues that underpin the "wicked problem" of insecticide use, BPH outbreaks and the prospects of using ecological engineering approaches.

Integrated Pest Management

Innovative agro-ecological strategies for management of cereal stem borers

Johnnie Van den Berg[1], Jessica Cockburn[2], Des Conlong[3]

[1]North-West University, South Africa, [2]North-West University, South Africa, [3]South African Sugarcane Research Institute, South Africa

The basic foundation of successful IPM implementation is a thorough knowledge of the target pest's life cycle, and its ecological and behavioral interactions with the environment and natural controlling factors in crop and especially indigenous habitats followed with sound technology transfer to target farmers. Increased species diversity in and around cropping systems and structured habitat management systems are becoming more important as IPM tools. These tools include agro-ecosystem management to make the crop less suitable for pest colonization, and to increase natural enemy foraging and abundance in the crop habitat, thereby increasing efficacy of conservation, inoculative and augmentative biological control. A novel habitat management strategy, using several components of the push-pull approach developed in east Africa, has been developed for Eldana saccharina (Lepidoptera: Pyralidae) in South African sugarcane. In this strategy indigenous host plants of E. saccharina, for example Cyperus dives (Cyperaceae) are used as 'pull' or attractive plants, while Melinis minutiflora (Poaceae) functions as a 'push' or repellent plant for the moths. Genetically modified Bt maize producing a toxin lethal to E. saccharina larvae, is used as a dead-end trap crop in the system. Increased biodiversity in agro-ecosystems generally leads to efficient natural control of crop pests and diseases. Need assessments and good technology transfer complements successful IPM adoption.

Key agronomic and ecological factors impacting moth borers populations and their natural enemies in the context of sugarcane expansion and intensification.

Francois-Regis Goebel
CIRAD, France

Global intensification and expansion of agricultural areas for more food and energy products is expected to change pest-plant interactions and the related ecosystem services. For example, intensification of agronomic practices, land use change, landscape fragmentation, incorporation of crop genetic improvements and altered harvest regimes lead to predictable shifts in pest and beneficial natural enemy communities in new sugarcane areas. This is particularly the case in the developing countries where natural vegetation patches are rapidly converted into agricultural land. In this context, the risk of biodiversity loss associated with pest outbreaks is often mentioned. Through different experiences in several sugarcane producing countries, it is shown how over application of fertilizers, water stress, misuse of insecticides, harvest delay, trash blanketing cane burning, use of susceptible varieties, Silicon deficient soils can dramatically increased infestation from major moth borers such as Eldana saccharina (Lepidoptera: Pyralidae) and Chilo sacchariphagus (Lepidoptera: Crambidae) with sometimes severe yield losses. This situation is often exacerbated by the lack of natural enemies, particularly in large-scale monoculture systems where natural vegetation has been cleared. The impact of such factors on arthropod communities should be carefully analyzed and incorporated in a new ecologically-based pest management approach at a landscape scale. This calls for increased scientific understanding of landscape effects on spatial crop?pest?natural enemy interactions and their ecosystem services such as biocontrol in the sugarcane areas.

Integrated Pest Management

Bio-intensive integrated pest management of invasive alien plants and indigenous insect pests of Graminaceous crops in a single programme: Fact or fantasy?

Desmond Edward Conlong
South African Sugarcane Research Institute, South Africa

Bio-intensive integrated pest management (IPM) is based on holistic agro-ecosystem interactions, in which knowledge about insects, their symbionts, pathogens, natural enemies, plants, endophytes and interactions between these are combined to develop IPM in an area-wide (AW), sustainable manner. Habitat management is advocated as part of AW-IPM by influencing behaviour of natural enemies and their hosts in such a way as to increase effectiveness of natural enemies in a crop. This paper proposes that biological control of invasive alien plants (IAP's) can contribute to habitat management as part of a bio-intensive AW-IPM for an indigenous stemborer, and that knowledge of the chemical ecology of the agro-ecosystem will enhance AW-IPM. Eldana saccharina (Lepidoptera: Pyralidae) is native to wetland plants in Africa. Its wetland habitat has been encroached (and surrounded) by crops providing food, and IAP's such as Eichornia crassipes, Pistia stratiotes, Lantana camara and Chromolaena odorata. These are generally more competitive than the indigenous wetland sedges that provide stable habitats for this borer and its natural enemies. It will be shown that augmentative mass releases of classical biocontrol agents of IAP's reduce the cover of these, providing opportunity for re-establishment of indigenous wetland plants, and thus habitat for indigenous natural enemy/host interactions, and how these will help manage pest populations in adjacent crop habitats. Furthermore, the complex nature of host location by parasitoids using volatiles emitted from indigenous compared to crop hosts in these agro?ecosystems will demonstrate the importance of a knowledge of chemical ecology in any bio-intensive AW-IPM strategy.

Sterile insect technique in sugarcane pest management

Desmond Edward Conlong[1], Angela Jasmin Walton[2], Pride Mudavanhu[3], Linke Potgieter[4]

[1]South African Sugarcane Research Institute, South Africa, [2]South African Sugarcane Research Institute, South Africa, [3]Stellenbosch University, South Africa, [4]Stellenbosch University, South Africa

Stemborers are constraints to world sugarcane production. Conventional control and integrated pest management (IPM) measures have worked in certain countries, but in others stemborers remain problematic and biosecurity risks. A bio-intensive control approach is advocated, based on holistic agro-ecosystem interactions, to develop IPM in an area-wide (AW) sustainable manner against these. Included here is Sterile Insect Technique (SIT). Eldana saccharina (Lepidoptera: Pyralidae), severely limits sugarcane production in South Africa. This paper shows SIT as a viable control option. Calco Red N1700, fed to E. saccharina larvae in a diet, coloured adult fat bodies red, with no ill-effects on development and reproductive biology. They could thus be separated from field adults. Radiation biology studies showed that F1 male sterility was attained by exposing "fathers" to 200 Gy. Minimal emergence from F1 progeny of males exposed to 150Gy makes this radiation dose an alternative. Males irradiated at 150 and 200 Gy commenced calling at the same time as untreated laboratory reared males, and at least six hours before field males. Similarly, irradiated males commenced mating with field females within 30 minutes of calling initiation, and much earlier than wild males. They mated with three to five times more wild females than wild males, and remained in copula with wild females for an hour longer than wild males. In choice experiments irradiated males were as competitive at attracting and mating with wild females as wild males were. SIT, using F1 sterility, can thus be developed as part of AW-IPM against E. saccharina

Integrated pest management of sugarcane moth borers: An Indonesian experience

Nader Sallam[1], Etik Achadian[2], Peter Samson[3], Regis Goebel[4]
[1]BSES Limited, Australia, [2]ISRI, Indonesia, [3]BSES Limited, Australia, [4]CIRAD, France

An Integrated Pest Management program is developed to combat moth borer infestation in Java, Indonesia. An extensive survey over a period of two years (2010 ? 2011) revealed the existence of five moth borer species causing damage to sugarcane crops in Java, and these were Chilo auricilius, C. sacchariphagus, Scirpophaga excerptalis, Sesamia inferens and Tetramoera schistaceana, with the three former species being the most abundant. Infestation by C. sacchariphagus and C. auricilius caused dead heart and leaf damage in young cane and bored internodes in older cane, while S. excerptalis was responsible for the majority of dead heart symptoms at all stages of plant development. Infestation by the main three borers commenced in February and escalated to a peak in about June ? July. Our results revealed very low levels of parasitism by key natural enemies, and this was attributed to inconsistent parasitoid release, lack of prior assessment of infestation levels, release of low parasitoid densities and random use of insecticides. Certain varieties demonstrated a degree of tolerance to borer infestation, however, different susceptibility levels to different borer species was evident, hence, breeding for combined resistance to all borer species is difficult. A plan is developed based on borer abundance in the field, whereby accurate densities of natural enemies are released as borer infestation commences and well before it reaches a peak. The principal components of a detailed Integrated Management Program to combat moth borer infestations in Indonesia are discussed.

Varietal resistance to stemborers in Papua New Guinea

Peter Samson[1], Kaile Korowi[2], Lastus Kuniata[3]
[1]BSES, Australia, [2]Ramu Agri-Industries, Papua New Guinea, [3]Ramu Agri-Industries, Papua New Guinea

Commercial crops of sugarcane at Ramu Agri-Industries, Papua New Guinea, are attacked by several species of moth borers, mainly Sesamia grisescens, Chilo terrenellus and Scirpophaga excerptalis, as well as the sugarcane weevil borer Rhabdoscelus obscurus. We analysed the results of variety trials planted in 2003, 2007, 2010 and 2011 with the aim of evaluating varietal responses to these borers, and particularly to S. grisescens. For all species, damage and/or numbers of insects differed significantly among clones in at least one trial. Levels of internode damage by S. grisescens to 12 standard clones, chosen to represent a range of responses to that borer, were correlated between most of the trials and crop classes. There were correlations, both positive and negative, between damage from the different borers. Cane yields, where measured, were negatively correlated with damage from S. grisescens but not C. terrenellus or S. excerptalis. These results confirm the importance of S. grisescens as a major pest of sugarcane in PNG, as well as the existence of resistance to this pest among sugarcane clones. In 2011, we also began artificial infestation experiments using eggs of S. grisescens in an attempt to develop a rapid screening method for resistance to this pest without interference from the other species. However, infestation procedures have so far proved unsatisfactory.

Keywords:*Moth borer, weevil borer, Sesamia grisescens, Chilo terrenellus, Scirpophaga excerptalis*

Significant improvement of IPM strategies against the sugarcane stem borer, *Chilo sacchariphagus*, through long-term succesful storage of *Trichogramma chilonis* (Hymenoptera:Tric)

Hong Do Thi Khanh[1], Adrien Bonnet[2], Johanna Bodendorfer[3], Etty Colombel[4], Francois-Regis Goebel[5], Marlene Marquier[6], Clarisse Clain[7], Estelle Roux[8], Elisabeth Tabone[9]

[1]INRA, Plant Protection Center, France, [2]INRA, France, [3]INRA, France, [4]INRA, France, [5]CIRAD, France, [6]FDGDON-Reunion, France, [7]FDGDON-Reunion, France, [8]FDGDON-Reunion, France, [9]INRA, France

The stem borer Chilo sacchariphagus is a key pest of sugarcane in Reunion Island and South-East Asia. Since 2002, an IPM strategy associating inundative release of an egg parasitoid, Trichogramma chilonis, and conservation of a predatory ant has been proposed. This reduced up to 50% of damage in field experiments in Reunion Island (financial gains from $800 to $1800/ha). To develop IPM strategies on a large scale, reducing the global costs is necessary. In this context, cold storage is a key step to the development of the sugarcane borer biocontrol, by improving production and release management. Thanks to a French funding (CASDAR), laboratory tests on cold storage of T. chilonis were first conducted, followed by field experiments on the performance of stored parasitoids. Quality control after storage was performed several times (after mass production, before and after transport, after field release) in laboratory at 25 ± 1°C, RH 75 ± 5 % and 16L: 8hD to evaluate emergence rate of stored insects, fecundity during 7 days and survival at 7th day of T. chilonis females. For the first time, a long-term cold storage of T. chilonis was obtained without loss of physiological performance (good emergence, fecundity, survival during 7 days). Results suggested a quiescence state because no loss was observed due to storage interruption. Moreover, the same field efficacy of cold stored Trichogramma compared to non-stored individuals was obtained in Reunion Island. These important results make possible a large-scale application of IPM strategies in sugarcane production.

Key steps of a successful biological control against the sugarcane stemborer by inundative release of *Trichogramma* spp.

Elisabeth Tabone[1], Marlene Marquier[2], Clarisse Clain[3], Estelle Roux[4], Francois-Regis Goebel[5], Jacques Frandon[6], Etty Colombel[7], Hong Do Thi Khanh[8]

[1]INRA - Nice, France, [2]FDGDON-Reunion , France, [3]FDGDON-Reunion, France, [4]FDGDON-Reunion, France, [5]CIRAD, France, [6]Compagny BIOTOP, France, [7]INRA - Nice, France, [8]INRA - Nice, France

For over ten years, a biological control strategy by inundative release of Trichogramma chilonis (Hymenoptera: Trichogrammatidae) against Chilo sacchariphagus (Lepidoptera: Crambidae) has been studied (French collaboration between INRA, CIRAD and FDGDON Reunion Island). Many key steps were elaborated the last years regarding the pest and beneficial insects. Strategies of biological control, mass production, and field releases were also investigated. Important results were obtained such as: (i) population dynamic of Chilo sacchariphagus and damage, (ii) efficacy of the egg parasitoid Trichogramma chilonis, (iii) strategies of insect release (period, dose, frequency, adapted packaging, and delayed emergence), (iv) optimization of mass production, (v) cold storage, (vi) field release methods and checking of field efficacy. An IPM strategy associating inundative release of an egg parasitoid, T. chilonis and conservation of a predatory ant, Pheidole megacephala, has been proposed. According to field experiments in Reunion Island, this reduced up to 50% of damage with financial gains ranging from 800 to 1800 dollars per ha. Successful long-term storage of T. chilonis and its good efficacy in field after cold storage make possible a large-scale application of IPM strategies in sugarcane production.

IPM module for the sustainable management of sugarcane stem borer, *Chilo infuscatellus* (Pyralidae , Lepidoptera) in Pakistan

Shahbaz Ahmad
Institute of Agricultural Sciences, University of the Punjab, Pakistan

The present study describes the evaluation of some environmentally sound tactics towards the management of sugarcane stem borer (Chilo infuscatellus). Different approaches were applied, Trichogramma cards, Detrashing, Light traps and Chemical control. The effects of these were found on the basis of incidence and intensity of Chilo infuscatellus. It was concluded from the results that the minimum infestation (8.71%) was recorded in T7 (Trichogramma cards + Detrashing + Light traps) which was statically at par with those of T3(Trichogramma cards + Light Traps), T1(Trichogramma cards + Detrashing) and T4(Detrashing + Chemical control) with increase in percent infestation 8.92%, 9.34% and 9.74% respectively. The treatment T8(Trichogramma cards + Chemical control + Light traps) showed 10.46% infestation was significant different from T6(Trichogramma cards + Detrashing + Chemical control), T9(Chemical control + Light trap + Detrashing) with infestation 11.66% and 11.86%. The treatment T2 (Trichogramma cards + Chemical control) with infestation 12.39% was statically at par with those of T5(Detrashing + light traps) with infestation (12.82%). The maximum infestation was observed in control treatment with 25.45%. The minimum infestation (11.66%) was recorded after 10 days interval while maximum infestation (12.53%) was observed after 20 days interval.

Study of adaptive odor searching behavior using a brain-machine hybrid system

Ryo Minegishi[1], Yosuke Takahashi[2], Atsushi Takashima[3], Daisuke Kurabayashi[4], Ryohei Kanzaki[5]

[1]Tokyo Institute of Technology, Japan, [2]Tokyo Institute of Technology, Japan, [3]Kyushu University, Japan, [4]Tokyo Institute of Technology, Japan, [5]The University of Tokyo, Japan

Insects perform adaptive odor searching behavior by integrating multimodal information. This adaptive behavior is generated through the interaction among a brain, a body and environments. To examine the adaptive processing of an insect's brain, we developed a brain-machine hybrid system which is a mobile robot mounted a male silkworm moth's head as a controller and sensors. Male moths orient toward female moths detecting upon conspecific female moths' sex pheromone. The robot was controlled according to the steering signals recorded bilaterally from neck motor neurons, 2nd CNb (2nd cervical nerve b) connecting with the pre-motor areas in the brain. We set the spike-behavior conversion rule that the spiking rates were linearly translated into the robot's wheels rotation. We could observe the moths' programmed behavioral pattern and orientation behavior on this system. Using this system, we examined whether moths could modify command signals responding to the given disturbances or changes of behavioral parameters. As a result, moths responded to the given angular velocity by using visual feedback. Moreover, when we biased left and right motor outputs and doubled angular velocity during odor source localization, activities of the 2nd CNbs were modulated depending on the motor parameters, and in several examples the hybrid system still could reach the pheromone source. From the results, moths on the hybrid system could show compensative responses to keep its angular velocity. I will discuss how moths generate this adaptive behavior using olfactory and visual information.

Chemical plume tracing performance depending on angular velocity observed by a brain-machine hybrid system

Yosuke Takahashi[1], Ryo Minegishi[2], Atsushi Takashima[3], Daisuke Kurabayashi[4], Ryohei Kanzaki[5]

[1]Tokyo Institute of Technology, Japan, [2]Tokyo Institute of Technology, Japan, [3]Kyushu University, Japan, [4]Tokyo Institute of Technology, Japan, [5]The University of Tokyo, Japan

Silkworm moths exhibit adaptive behavior according to dynamic environments during the chemical plume tracing (CPT). The purpose of this study is to investigate whether the adaptability contributes to the CPT performance. We consider the adaptability should be implemented in order to realize an effective artificial CPT system. To investigate the moth's brain functions to modify its behavior, we identified the brain as a linear dynamic model by using a brain-machine hybrid system, which was composed of a moth's brain and a robotic body. The system enables us to investigate how the brain adapts to the changes of the body properties. In the experiment, we measured the neural responses to rotational disturbances to the system by changing the motor gain of the robot. Regarding the disturbances as input and the angular velocity which were calculated from the neural responses as output, we identified the transfer function. Comparing the two transfer functions obtained by changing the motor gain of the robot, we found that the parameters of the transfer functions were kept constant regardless of the motor gain. In short, the brain has the ability to keep the angular velocity responses constant. Then we evaluated by computer simulations whether the CPT performance was related to the angular velocity. As the results, we obtained the optimal value of the angular velocity during the CPT. In conclusion, adjusting the angular velocity of a robot to the average angular velocity of moths potentially improve the CPT performance.

Extraction of morphological characteristics of insect specimens for automatic identification by using wavelets and self-organized map

Chang Woo Ji[1], Young-Seuk Park[2], Bong-Gyu Byun[3], Hwang-Yong Kim[4], Tae-Soo Chon[5]

[1]Pusan National University, Republic of Korea, Republic of Korea, [2]Kyung Hee University, Republic of Korea, Republic of Korea, [3]Hannam University, Republic of Korea, [4]National Institute of Agricultural Science and Technology, Republic of Korea, [5]Pusan National University, Republic of Korea

Automatic identification of specimens is prerequisite in monitoring and guaranteeing reliable measurements of species composition in ecosystems. Wavelets and Self-Organizing Maps (SOMs) were utilized to extract the colored wing patterns of insect species for automatic identification in this study. Species in different families including Papilionidae and Pieridae in Lepidoptera were selected, and the images were accordingly pre-treated to minimize individual variation and noise. Wavelets were subsequently applied to feature extraction of the colored patterns. Wavelet coefficients were accordingly calculated based on the basis function (e.g., Morlet). The obtained coefficients were subsequently provided to Self-Organizing Map (SOM) for classification of the specimens. Although individual variation was observed, the combinational use of Wavelets and SOM was efficient in characterization of the colored patterns and identification of the insect specimens. Application of computational methods to automatic detection of specimens was further discussed regarding objective species assessment in ecological sciences.

Integrated Pest Management

Agricultural robot for pest management and in situ pest recognition

Chunlei Xia[1], Jang-Myung Lee[2], Bu-Keun Chung[3], Yoo-Han Song[4], Tae-Soo Chon[5]

[1]Pusan National University, Republic of Korea, [2]Pusan National University, Republic of Korea, [3]Gyeongnam Agricultural Research and Extension Services, Republic of Korea, [4]Gyeongsang National University, Republic of Korea, [5]Pusan National University, Republic of Korea

Pest damage is one of the main factors to cause severe production loss in agriculture. In this study, a greenhouse robot is developed for controlling pests with minimal dose of pesticides and for automatically detecting pest distribution in greenhouse. The 3 degree of freedom manipulator of the robot ensures the precise spray to individual leaves with minimal volume of chemicals. A sampling device (e.g, sticky trap) is additionally installed on the robot for attracting pests. The images of pests attracted to the sticky traps were analyzed by multifractal dimension. The tiny size of pests (i.e., whitefly) is efficiently recognized to be able to count the number of insects attached to the traps in unit time. As the robot patrols the greenhouse, the pest detection data are recorded concurrently, providing information on spatial distribution as the time progresses. The in situ pest distribution and pest dispersal were further discussed regarding prediction of pest density and pest control strategy.

Recognition of the line-shaped movement of aquatic macroinvertebrates in stressful conditions

Woon-Seok Cho[1], Bo-Moon Kim[2], chunlei xia[3], Hungsoo kim[4], Kyung-Hee Choi[5], Tae-Soo Chon[6]

[1]Pusan National University, Republic of Korea, [2]Pusan National University, Republic of Korea, [3]Pusan National University, Republic of Korea, [4]Pusan National University, Republic of Korea, [5]Cowellmedi Co., Ltd, Republic of Korea, [6]Pusan National University, Republic of Korea

Aquatic macroinvertebrates are considered as an efficient indicating taxon in response to environmental variability. Recently response behaviors have been regarded as an effective tool for monitoring disturbing agents in aquatic ecosystems. Behavior of individuals could change instantly in time (e.g., changing shape, speed, acceleration, turning angles) and could efficiently present the time progress of response behaviors to disturbances in situ. Most studies, however, have been conducted with the point data to indicate movement positions of the round shaped indicator species. In this study, behaviors of the line shaped species (e.g., chironomid larvae) were analyzed with the movement segments continuously recorded by the video-tracking system. The body components were analyzed before and after the treatments of toxic chemicals (including formaldehyde). Different behavior responses were detected after the toxin treatment along with time progress (e.g., irregular movement, shaking). Behaviors of chironomid were compared with behavior factors of other line-shaped organisms (e.g., C. elegans). The study on the line-shape movement would contribute to broadening the scope of behavior monitoring and would be suitable in development of early-warning system to detect disturbances in environment.

Analysis of movement behaviors in response to chemical stressors using self-organizing map and hidden Markov model

Yan Li[1], Tae-Soo Chon[2], Yuedan Liu[3], Jang-Myung Lee[4]

[1]Pusan National University, Republic of Korea, [2]Pusan National University, Republic of Korea, [3]Chinese Research Academy of Environmental Sciences, China, [4]Pusan National University, Republic of Korea

Movement tracks of indicator species, including Drosophila melanogaster, were continuously observed before and after the treatments of toxic chemicals (formaldehyde) at different concentrations (0.1, 1.0 and 2.5 ppm) based on computer vision techniques. The positional order of the movement was classified into different patterns in two dimensions. The Self-organizing map (SOM) was applied to classification of movement behaviors before and after treatment. Subsequently, a hidden Markov model (HMM) was utilized to sequence changes in behavior states of indicator species. The transition probability matrix (TPM) and the emission probability matrix (EPM) were accordingly obtained through HMM. Efficiency of HMM was further discussed in behavior monitoring effects of disturbances in environment.

Analysis of gene information of insects based on pattern recognition techniques

Dong-Hwan Kim[1], Tuyen Van Nguyen[2], Hungsoo Kim[3], Thao Thi Nguyen[4], Young-Su Seo[5], Kozo Watanabe[6], Tae-Soo Chon[7]
[1]Pusan National University, Republic of Korea, [2]Pusan National University, Republic of Korea, [3]Pusan National University, Republic of Korea, [4]Pusan National University, Republic of Korea, [5]Pusan National University, Republic of Korea, [6]Ehime University, Japan, [7]Pusan National University, Republic of Korea

The DNA sequence and amino acid data of insects including Chironomide (Diptera) were analyzed by Self-organizing map (SOM). Abundance distributions of genotypes at DNA and amino acids levels were further compared in different species according to different patterns obtained by the SOM. The SOM patterns accordingly characterized the species clusters, reflecting ecological (e.g., feeding types) and geographical (e.g., distribution) effects. The relationships between DNA sequence and amino acids were computationally addressed to reveal structural properties residing in hierarchy of DNA and amino acid. The models for abundance distribution patterns including log-normal distribution were obtained according to different taxa, and accordingly expressed the complexity of gene information. By distinguishing the differences at the layer of DNA sequences and amino acids, evolution and adaptation of the species could be efficiently addressed in response to environmental constraints.

Wavelet method applied to analysis of movement behavior of indicator species

Hungsoo Kim[1], Yuedan Liu[2], Zongming Ren[3], Tae-Soo Chon[4]

[1]Pusan National University, Republic of Korea, [2]Chinese Research Academy of Environmental Sciences, China, [3]Chinese Academy of Sciences, China, [4]Pusan National University, Republic of Korea

We analyzed the time development of movement behavior of indicator species using the wavelet method. Movement of indicator species (Daphnia magna) was continuously recorded and the movement tracks were transformed to time series of coordinates. We analyzed the time series of movement track data using the wavelet method and subsequently introduced quantum mechanical analogy to quantify the movement tracks. Each mode in the wavelet method was considered as a quantum mechanical state while the amplitude of each mode as the probability. The quantum mechanical entropy, von Neumann entropy, could be evaluated and the entropy was compared with others including Shannon entropy and Permutation entropy. We also discussed about application of the method for monitoring chemical stress in response behaviors of the indicator species.

Computational methods for analyzing morphology and behavior of macroinvertebrates and insects for monitoring

Tae-Soo Chon

Pusan National University, Republic of Korea

Automatic image processing has been developed rapidly for monitoring in various fields since late 1990's, including pest management, species diversity maintenance, and risk assessment. Recent development of computation models are outlined in detection of insects and macroinvertebrates and in tracking movement behaviors under various environmental conditions. In addition to statistical analyses, the methods include information extraction, patterning, stochastic processes, and time series analyses. For information extraction entropy (e.g., permutation entropy) and multi-fractal dimension were used to express the structure property residing in the behavioral data. Ecological informatics including self-organizing map and multi-layer perceptron network and wavelets were applied to patterning the complex data under stressful conditions. For elucidating stochastic processes in behavioral changes, hidden Markov models were implemented to address transition probability in behavioral changes. For time series analyses temporal networks such as recurrent neural network and cross-correlation analyses were used for predicting time delay effects of behavioral changes. Efficiency of in situ behavioral monitoring was further discussed for application including pro-ecological pest control and conservation management.

Range expansion of the southern green stink bug *Nezara viridula* in Japan with advance in the climate warming

Kenji Fujisaki
Kyoto University, Japan

The impact of climate warming on insects was studied using the southern green stink bug Nezara viridula which is a tropical species in its origin. At first, past and current limits of the distribution range of this species were compared. As a result, it was found that the climate warming promoted northward range expansion of Nezara viridula by providing favourable overwintering conditions close to the specie's range limit. At the same time, the life history traits such as an intensity of reproductive diapause is on the way of changing with northward range expansion. Furthermore, this range expansion of Nezara viridula is now accelerating the extinction of temperate closely related species, Nezara antennata, by the infertile interspecific copulation. The progeny of field collected adults was reared under outdoor conditions and under virtual climate warming conditions (incubator which simulated climate warming by adding in real time 2.5℃ to the outdoor conditions). Even such a moderate temperature increase affected many life history traits of Nezara viridula. The warming advanced development in autumn and enhanced survival in winter, but retarded growth and increased mortality in summer even at the northern limit of species's range. Our current studies are going to clarify that such an adverse effect of high temperature is caused by the decrease in bacterial symbiont which is harboured in the midgut of stink bugs.

Pecky rice problem in Japan

Hiroya Higuchi
Agricultural Research Center, Japan

Two mirid bugs, Trigonotylus caelestialium and Stenotus rubrovittatus (Heteroptera: Miridae), are important pests that infest rice crops in Japan. In particular, the rice leaf bug, T. caelestialium, reproduces on gramineous plants and invades rice paddy fields after rice plant heading. Damage from the bug feeding causes stained grains, known as pecky rice. The females emit sex pheromone and attract conspecific males. Hexyl hexanoate, (E)-2-hexenyl hexanoate and octyl butyrate were identified as female sex pheromone components and the synthetic sex pheromone also attracts conspecific males. Sweeping of vegetation with an insect net is one of the conventional methods of surveying for insect pests in rice. Pheromone traps are easy to use and also eliminate the need for specialized training to detect and identify the target insects. A sticky trap with a rubber septum impregnated with the synthetic sex pheromone was placed in the center of a paddy field. The fluctuation pattern of males caught in traps and the number of males captured by sweeping were synchronized. This result suggests that the pheromone trap can be utilized as a monitoring tool for the rice bugs in paddy fields. Therefore, we have clarified the relation between the number of bugs caught in traps and the percentage of pecky rice, and developed the technique to determine the necessity and timing of chemical control.

Research status on stink bugs in Korea

Chung Gyoo Park[1], Dong Soo Kim[2]
[1]*Graduate School of Gyeongsang National University, Republic of Korea,* [2]*Korea Forest Research Institute, Republic of Korea*

Some species of true bugs have been gradually becoming serious problems worldwide on several crops. Some bugs are important as biological control agents of insect pests. Reviewing articles would be meaningful for the set-up of research direction for this insect group in the future. Thus, we reviewed the articles on true bugs studied in Korea since 1960. A total 122 papers on pest or natural enemy bugs have been published in scientific journals. Number of papers per decade is increasing, recording 82 papers since 2000. A nearly one third of total papers is related to the bean bug, Riptortus pedestris, mostly focused on its aggregation pheromone and natural enemies. This is perhaps because R. pedestris is an important pest of soybean, non-astringent (sweet) persimmon or sometimes of apple. Among cultivated crops, rice plant and soybean were most frequently dealt with by researchers. We categorized all the papers into several subjects; classification and morphology, development or growth analysis, bug fauna and damage in some crops, seasonal occurrence patterns, egg parasitoids of stink bugs and predatory bugs. Recently, research on the aggregation pheromone of R. pedestris has been actively done; the pheromone component composition of Korean population, attractiveness of the pheromone to itself and to other stink bug like Piezodorus hybneri and a parasitoid, Ooencyrtus nezarae (Encyrtidae). Attraction of the tachinid fly Gymnosoma rotundatim was reported to the pheromone of P. stali (Pentatomidae). Research on using the refrigerated R. pedestris eggs is actively going on to augment its parasitism in soybean field.

Keywords:*True bug, Sweet (non-astringent) persimmon, Soybean, Riptortus pedestris, Plautia stali, Parasitoids*

Recent advances on phytophagous stink bug feeding and damage in South America

Antonio Ricardo Panizzi
Embrapa, Brazil

Stink bugs (Heteroptera: Pentatomidae) are considered pests of economic importance of major commodities in the neotropics, such as soybean, wheat, corn, and cotton. They feed by introducing their mouthparts (stylets composed of a pair of mandibles and a pair of maxillae) on plant tissues, either vegetative, such as leaves and stems, or reproductive, such as seeds and fruits. Heteropterans use four types of feeding: stylet sheath, lacerate-and-flush, macerate-and-flush, and osmotic pump feeding. Before introducing the stylets, bugs probe the food with their mouthparts, and the information whether the food is suitable or not is apparently detected by gustatory sensila, present on the tip of the rostrum. After probing, stylet penetration occurs. The potential penetration of the stylets has been estimated based on the rostrum length, and on the probing position plus length of mouthparts segments. The resulting damage is caused by feeding time, mechanical and chemical stress. Mechanical stress is related to the mandible serration, that destroy plant tissue as they penetrate and move inside the tissue; chemical stress is due to the action of salivary enzymes that destroy the cell contents. Feeding damage to soybean seeds by four species of pentatomids [Dichelops melacanthus (Dallas), Euschistus heros (F.), Nezara viridula (L.), and Piezodorus guildinii (West.] will be presented and discussed in detail. Data showing wear of mandibles of stink bugs due to feeding activity on different food sources will be presented and discussed, as well.

Current pest status of *Halyomorpha halys* in the USA

George C. Hamilton
Rutgers University, U.S.A.

Since its initial discovery in the late 1990's in Allentown, PA and subsequent identification in 2001, the brown marmorated stink bug (BMSB), Halyomorpha halys (Stal) has been detected in over thirty five states in the continental United States. In most states, BMSB is considered a nuisance pest. However, BMSB was shown to potentially impact tree fruit in Pennsylvania and New Jersey in 2006 and 2007. In 2010, BMSB populations exploded in the mid-Atlantic Unites States impacting a wide variety of agricultural crops throughout the mid-Atlantic area. The impact and ramifications of this population explosion will be discussed.

Egg parasitoids of stink bugs: Research status and potential for biological control

Eric Conti[1], Stefano Colazza[2]
[1]*University of Perugia, Italy,* [2]*University of Palermo, Italy*

Egg parasitoids are among the most important natural enemies associated with herbivorous stink bugs, and they show remarkable potential as biological control agents. On the other side, some egg parasitoid species also attack predaceous bugs, thus affecting the efficacy of these important entomophagous insects. Most studied stink bug egg parasitoids belong to Platygastridae (=Scelionidae) and Encyrtidae, the main research topics concerning behavior, chemical ecology, behavioural ecology and field efficacy. Some species have been used for biological control programs. However, some constraints may prevent egg parasitoids from becoming effective agents in inundative biocontrol projects, the most important being incomplete behavioral and ecological knowledge for most species and inefficient mass production. Thus, understanding the host selection strategies of egg parasitoids and the chemical stimuli involved would lead to enhanced biological control through behavioral manipulation of egg parasitoids in the field, and to the development of better rearing methods. Egg parasitoids of herbivorous stink bugs may adopt differing host selection strategies, the most important being the exploitation of kairomones from non-target instars in combination with host-induced plant synomones (indirect resistance), and associative learning. The chemically mediated behavior of these wasps may be exploited, e.g., through the development of plants with elevated expression of indirect induced resistance, or spraying fields with resistance elicitors. Important elements toward implementation include procedures for selection of egg parasitoids, evaluation of their specificity, risk assessment of new introductions, release methods, and quality control. Implementation of knowledge acquired from laboratory studies must finally be scaled up and transferred to growers.

Provision of host eggs to increase field parasitism of the bean bug: Theory and practice

Un Taek Lim
Andong National University, Republic of Korea

Augmentative biological control of Riptortus pedestris Thunberg (Heteroptera: Alydidae) using parasitoids is not economically feasible in field crops like soybeans in Korea due to the cost of rearing parasitoids and the relatively low cash value of soybeans. As a conservational biological control, the release of cold-stored eggs of R. pedestris has been suggested because the eggs become non-viable but can still be parasitized by parasitoids. This method has potential advantages: (1) it is cost effective and has no quality issues such as inbreeding depression and alteration of foraging behavior of parasitoids, and (2) it would minimize disturbance to the parasitoid community caused by the release of a certain parasitoid species. We evaluated inoculation of cold-stored eggs as a method to enhance field parasitism. First, about 10,000 cold-stored eggs were inoculated in soybean fields (2,028-3,540 m2) in 2006. A higher seasonal parasitism rate was found at the treated sites although pest populations were not affected. Second, because aggregation pheromone, produced by males of R. pedestris, also attracts egg parasitoids, we used cold-stored host eggs in the pheromone trap together to both trap bugs and propagate parasitoids on host eggs attached to the trap. About 10,000 non-viable eggs were used in soybean fields (1,677-2,844 m2) in 2008. Again, although significantly higher parasitism (78-91%) occurred in the treatment sites compared to control sites (0-62%), no statistical significance of treatment was found in R. pedestris population. Explanations for these outcomes and future studies needed to be done are discussed.

Detecting source habitat of the bean bug *Riptortus pedestris* and its egg parasitoid: Toward area-wide pest management using natural pest control

Ken Tabuchi[1], Hisatomo Taki[2], Hideki Iwai[3], Nobuo Mizutani[4], Koukichi Nagasaka[5], Seiichi Moriya[6], Rikiya Sasaki[7]

[1]NARO Tohoku Agricultural Research Center, Japan, [2]Forestry and Forest Products Research Institute, Japan, [3]NARO Agricultural Research Center, Japan, [4]NARO Kyushu Okinawa Agricultural Research Center, Japan, [5]NARO Agricultural Research Center, Japan, [6]NARO Agricultural Research Center, Japan, [7]Fuji Flavor Co., Ltd, Japan

Natural pest control is a major alternative to the chemical control of agricultural pests, but it needs improvement. Quantifying the abundance of insect pests and invertebrate natural enemies in source habitat would be essential for designing environmentally friendly crop-protection systems. To evaluate the availability of natural pest control for the soybean pest Riptortus pedestris (Hemiptera: Alydidae) by their major egg parasitoid Ooencyrtus nezarae (Hymenoptera: Encyrtidae) in source and arable habitats, we compared their abundance in soybean fields and at forest edges, which were assumed to be the overwintering site of R. pedestris in previous studies. We set traps baited with synthetic attractant for both species in soybean fields and along forest edges in mid-August over 2 years. During one of the two years, we also examined the degree of natural pest control by examining the rate of parasitism using an egg trap. The results showed that the numbers of both R. pedestris and O. nezarae trapped at forest edges were higher than those in soybean fields. Our result also showed that better pest control service by O. nezarae was provided at forest edges than in soybean fields. Therefore, when utilizing pest-control by O. nezarae in soybean fields, it is important to consider the spatial arrangement and distance to the forest edge. We would like to discuss about the importance of quantifying the abundance of insect pests and their natural enemies in source habitats beyond single-field boundaries when controlling insect pests using natural enemies.

Seasonal habitat use by stink bug pests and their egg parasitoids: Implications for managing these mobile pests in diversified agroecosystems

Yoshimi Hirose
Kyushu University, Japan

Stink bug pests are most notable among mobile pests defiend as polyphagous and multivoltine pests that move freely over large areas and between crops in diversified agroecosystems. Natural enemies of mobile pests have difficulty in shifting their habitats to follow the seasonal movements of the pests, and egg parasitoids are most important among natural enemies of stink bug pests. Thus, determining how stink bug pests and their egg parasitoids seasonally use their habitats is necessary for managing these mobile pests. Based on field surveys of egg parasitism of stink bug pests in Japan, I examined habitat use by these pests and their egg parasitoids during a growing season. Results of the surveys showed that some parasitoid species can shift their habitats to follow the seasonal host movement but others cannot. When a parasitoid species cannot shift its habitat to follow the seasonal host movement, its hosts escape parasitism in a new habitat. Proper host management is required for this habitat unless other parasitoid species reach the habitat. For managing stink bug pests, information on habitat use by their egg parasitoids during hibernation also is needed. Hibernation habitats of these egg parasitoids are different from their habitats during a growing season. Under the bark of zelkova trees in village shrines, I found overwintering aggregations of female adults of Trissolcus spp. which are egg parasitoids of some stink bug pests in Japan. On the basis of this finding, the importance of conserving the hibernation habitats of these egg parasitoids is emphasized.

Attractiveness of stink bugs to trap types and its utilization in fields

Soon-Do Bae[1], Hyun-Ju Kim[2], Young-Nam Yoon[3]

[1]Food Research and Development Institute, Republic of Korea, [2]Food Research and Development Institute, Republic of Korea, [3]Food Research and Development Institute, Republic of Korea

Six species of stink bugs are regarded as major stink bugs on soybean, Korea. These are classified into two families of alydidae and pentatomidae taxonomically. Bean bug, Riptortus pedestris Fabricius, belonging to alydidae has high flying and moving ability while penatomidae stink bugs such as one-banded stink bug, Piezodorus hybneri Gmelin, brown-mamorated stink bug, Halyomorpha halys Mista, sloe bug, Dolycoris baccarum Linnaeus, green stink bug, Nezara antennata Scott and brown-winged stink bug, Plautia stali Scott have low flying and moving ability relatively. Several types of traps are generally used for attraction of stink bugs in agricultural fields. Fish-net trap and funnel trap are effective for attraction of R. pedestris while barrier-funnel trap and disk trap are effective for attraction of pentatomidae stink bugs generally. Recently, M-S cone trap which is developed by our own is also evaluated as an effective attraction of R. pedestris in soybean field. Accordingly, attractive effect of stink bugs is closely related with trap types. In addition to, attractiveness of stink bugs are significantly influenced with amount and composition of aggregation pheromone, trap placing height and site, and different lure combinations. In particular, attractive effect of stink bugs are significantly increased with aggregation pheromone-soybean seeds combination trap placed at plant height in fields. Accordingly, these factors are properly considered for the effective management of stink bugs population in agricultural fields by mass trapping with lures including aggregation pheromone.

The pentatomid hunters: Molecular tracking of predation on stink bugs (Hemiptera: Pentatomidae) in cotton and soybeans

James Douglas Harwood[1], Kacie J Athey[2], John R Ruberson[3]
[1]University of Kentucky Lexington, U.S.A., [2]University of Kentucky Lexington, U.S.A., [3]University of Georgia, U.S.A.

Stink bugs (Hemiptera: Pentatomidae) have emerged as significant pests of cotton and soybeans in the southeastern United States with losses exceeding $70 million annually. Three of the most prominent pests are the southern green, Nezara viridula, green, Chinavia hilaris and brown stink bug, Euschistus servus. However, their predators are poorly understood, especially in respect to early season predation. As field observation of predation is difficult, molecular gut content analysis offers an alternative to traditional approaches. Consequently, species-specific 16S molecular markers were designed and used to discern the gut contents of potential predators of stink bugs. Various predators were collected throughout the summer in cotton and soybean in southeastern Georgia, and predation frequency was examined relative to prey availability. Predation rates were significantly higher on N. viridula than on E. servus and C. hilaris, despite relatively similar availability of all prey resources. Our results showed that N. viridula was consumed primarily by the predators Coleomegilla maculata, Geocoris punctipes, and Notoxus monodon, with up to 40% positive in July. These data suggest generalist predators could provide valuable biological control of stink bugs, but additional research examining the spatio-temporal nature of predator-prey interactions is required to understand the structure of such food webs relative to pest management.

Bt maize in the Americas from 1996 to 2012

Richard L. Hellmich
USDA-ARS,Corn Insects and Crop Genetics Research Unit, and Iowa State University, U.S.A.

Maize hybrids that are genetically engineered to produce crystal (Cry) proteins or toxins from the soil bacterium, Bacillus thuringiensis (Bt), have revolutionized pest control and currently are grown in more than a dozen countries on over 58 million acres. The primary targets of Bt maize are lepidopteran larvae that are stalk borers, ear or leaf feeders, and coleopteran larvae that feed on roots. Growers are attracted to Bt maize because of the reduced need for chemical insecticides, yield protection, improved grain quality, and convenience. Suppression of pest populations has benefited both Bt and non-Bt maize growers in the United States Corn Belt. Since the first commercial use of Bt maize in 1996 the variety of genetically-engineered maize products for insect control has increased substantially, which has expanded the spectrum of targeted pests and improved insect resistance management strategies. Yet in the Americas entomologists are learning that Bt maize must be used in concert with other insect management practices, a new approach to integrated pest management, because overreliance on a single tactic at least for some insect pests leads to insect resistance issues.

The changing landscape of cotton IPM in the GM crop era

Steven E. Naranjo
Arid-Land Agricultural Research Center, U.S.A.

The adoption of GM cotton continues to expand with 12 countries producing nearly 25M hectares in 2011. The global economic and environmental benefits continue to accrue as well with an estimated reduction of >150M kg in insecticide active ingredient and farm income benefits totaling nearly $20B over the last 14 years for insect-resistant Bt cotton. The deployment of Bt cotton has affected regional reductions in target pest populations in several countries and these reductions have sometimes benefitted producers of other crops, especially with polyphagous target pest such as cotton bollworm. Regional reductions in target pest populations have also opened the door for more permanent solutions to pest problems. For example, Bt cotton has been a key technology in permitting the eradication of the longtime invasive pink bollworm from the USA and northern Mexico. Dramatic reductions in insecticide use aimed at Bt targeted pest has also been associated with significant increases in ecosystems services such as biological control. These affects have cascaded within agroecosystems, allowing more ecologically-based management of numerous key pests that are unaffected by Bt proteins. For example, Bt cotton has played a central role in reducing insecticide use in Arizona cotton by nearly 90% in the last 15 years. Despite these gains, reductions in insecticide use have also precipitated or enhanced problems with other pest species that were once controlled by the broad-spectrum treatments for Bt targeted pests. This presentation will highlight benefits and costs associated with Bt cotton production globally.

Indirect, plant-mediated competition in Bt cotton - a possible mechanism underlying secondary pest outbreaks

Joerg Romeis[1], Steffen Hagenbucher[2], Felix L. Waeckers[3]
[1]Agroscope Art, Switzerland, [2]Agroscope Art, Switzerland, [3]Lancaster University, United Kingdom

Genetically engineered cotton plants that express lepidopteran-active Cry proteins from Bacillus thuringiensis (Bt) are grown on millions of hectares worldwide and have lead to area-wide population suppression of key pest species. Numerous studies have established that the Cry proteins expressed in commercialized Bt cotton varieties are highly specific to herbivores belonging to the order Lepidoptera. A potential negative effect of the adoption of Bt cotton varieties is the emergence of secondary-pests and it has been reported from different world regions that populations of some non-lepidopteran species have increased. This increase in non-target herbivore populations has generally been linked to the reduced use of broad-spectrum insecticides to control pest Lepidoptera. Potential indirect, plant-mediated effects of Bt cotton on non-target herbivores, however, have received little attention. We have studied the impact of the insecticidal trait on the natural inducible defense mechanisms of cotton. Cotton is defended by a range of terpenoids (e.g., gossypol) that are induced by herbivore damage. We show that the reduction of damage caused by the elimination of caterpillars in Bt cotton can lead to a lower concentration of cotton terpenoids, thereby making the plant more vulnerable to attack by other herbivores such as aphids, which do not induce a defense response by the plant.

Bt rice in China: Potential benefits, impact, and sustainability

Gongyin Ye[1], Mao Chen[2], Yang Chen[3], Junce Tian[4], Yufa Peng[5]

[1]Zhejiang University, China, [2]Zhejiang University, China, [3]Zhejiang University, China, [4]Zhejiang University, China, [5]Chinese Academy of Agricultural Sciences, China

From the ?rst insect-resistant genetically modi?ed (IRGM) rice transformation in 1989 in China. Numerous lines of genetically modified rice expressing cry genes from Bacillus thuringiensis (Bt) have been shown to confer resistance to lepidopterous pests under laboratory and field conditions. Until October 2009, the Chinese Ministry of Agriculture issued biosafety certi?cates for two transgenic cry1Ab/Ac rice ines, and China made a great leap forward from insect-resistant genetically modified (IRGM) rice basic research to potential commercialization of the world's ? rst IRGM rice. Research has been conducted on developing IRGM rice, assessing its environmental safety (mainly on non-targets herbivores, natural enemies, domestic silkworm and arthropod diversity as well as gene flow to wild rice) and food safety impacts, and evaluating its socioeconomic consequences. Laboratory and ?eld tests have con?rmed that these two Bt rice lines and other Bt rice lines can provide effective and economic control of the lepidopteran complex on rice with less risk to the environment than present practices. Commercializing these Bt plants, while developing other GM plants that address the broader complex of insects and other pests, will need to be done within a comprehensive integrated pest management program to ensure the food security of China and the world.

Bt transgenic grain legumes in pest management : Progress and problems

Hari C. Sharma
International Crops Research Institute for the Semi-Arid Tropics, India

Insecticidal genes from the bacterium, Bacillus thuringiensis have been inserted into grain legumes such as chickpea, pigeonpea, cowpea, faba bean, lentil, soybean, and groundnut. However, transgenic grain legumes have not yet been deployed for pest management. While efficacy of transgenic copwpea, chickpea and soybean groundnut has been proved under greenhouse conditions, only transgenic copwpea is being tested under field conditions in West Africa. To ensure a sustainable deployment of transgenic insect-resistant grain legumes, it is important that they are compatible with other control methods, including biological control agents that are of importance for natural regulation of pest populations. Toxin genes from Bt are considered to be environmentally benign and their use will reduce the hazards associated with the use of synthetic insecticides. However, it is important to follow bio-safety regulations, and there is a need for better presentation of the benefits of biotechnology to the general public for rational deployment of the transgenic plants for pest management and sustainable crop production. Incorporation of insecticidal genes in crop plants will have a tremendous effect on pest management. Emphasis should be placed on combining exotic genes with conventional host plant resistance, and also with traits conferring resistance to other insect pests and diseases of importance in a crop in the target region. There is a need to follow the biosafety regulations and make this technology available to farmers at a reasonable price, who cannot afford the high cost of seeds and chemical pesticides.

Bt vegetables for insect management within IPM programs: Successes, disappointments, challenges and ways to move forward

Anthony M. Shelton
Cornell University, U.S.A.

Genetically engineered (GE) insect-resistant plants that express proteins from Bacillus thuringiensis (Bt) have been widely adopted for corn and cotton. However, the development and commercialization of Bt vegetables has lagged in comparison, which is unfortunate since vegetables tend to be insecticide-intensive crops due to high pest pressure and cosmetic standards required for the market. While it is often stated that consumer choice has played a major role in companies avoiding development of Bt vegetables, this concept requires re-evaluation. When consumers in North America have been provided basic information about Bt plants and given a choice between Bt and conventionally sprayed sweet corn, they have often preferred the former. Likewise, 77% of consumers in a US survey said they would likely purchase foods produced through biotechnology if it can reduce pesticide use. Presently, however, the only commercialized Bt vegetable is sweet corn. More critical obstacles to Bt vegetables are their relatively smaller acreages and the cost of government biosafety regulations that inadvertently favor large acreages of field crops because companies can obtain a better return on investment. In developing countries, private-public partnerships may provide a way to bring Bt vegetables to market. However, these can be subverted by misinformation from anti-biotech campaigns, as is the case with Bt eggplant in India. Without the use of Bt vegetables as a tool for integrated pest management, farmers and the general public will not be able to realize the substantial environmental and economic benefits that are well documented with Bt cotton and Bt corn.

The two seasons of multilocation field trials in Luzon Island, Philippines of open-pollinated transformed eggplants expressing the Cry 1Ac insecticidal protein from Bacillus thuringiensis subsp. kurstaki (Bt) were completed during the 2010-2011 cropping seasons. The field evaluations showed consistently high efficacy of the Bt eggplants against the field populations of fruit and shoot borer (FSB), Leucinodes orbonalis Guenee across seasons over three locations as compared to their nonBt counterpart. The parameters used to measure field resistance were shoot damage, fruits with holes and extent of larval tunnelling expressed as percentages. In addition, the effect of additional protection from chemical control with the use of Bt eggplant was also determined. The results showed that weekly insecticide application did not significantly reduced the high percent damage in nonBt eggplant while both treated and untreated Bt eggplant showed consistently reduced larval damage.

Insect-resistant GM crops and IPM: The chemistry should be right

Marcel Dicke
Wageningen University, Netherlands

Integrated pest management (IPM) has shown excellent results in the development of durable management of insect pests. Yet, although successful IPM strategies have been developed worldwide, further improvement of IPM is ongoing and may be implemented in new crops. The use of transgenic technology to create insect-resistant crops can offer a solution to the limited availability of highly insect-resistant cultivars. On the other hand, the development of transgenic insect-resistant crops may provide a first step in the development of new IPM programmes to replace current control strategies that are based on chemical pest control. After the elimination of the primary pest through a GM approach, secondary pests need to be controlled through additional control methods, preferably methods that further support the development of an environmentally benign pest management strategy. This resembles the development of many IPM programmes. The GM approach and the IPM approach have usually been developed in separation rather than in collaboration. Yet, when the chemistry is right GM and IPM can prove to yield a fruitful integration that can lead to the enhancement of durable, environmentally benign methods of pest management.

Insect resistance management for GE crops: Patterns of success

Richard Tyrone Roush
University of Melbourne, Australia

After 15 years of field use, resistance to crops expressing insecticidal proteins modelled on those from Bacillus thuringiensis (Bt) has now evolved in at least 4 cases in the field. These include 3 Lepidoptera, the pink bollworm, Pectinophora gossypiella, to Bt cotton in western India, and to Bt maize, the armyworm, Spodoptera frugiperda, in Puerto Rico, and the stem borer, Busseola fusca, in South Africa. Among beetles, we have resistance to Bt maize in the chrysomelid Western corn rootworm, Diabrotica virgifera, in the USA. In other species and locations, increases in resistance allele frequencies have been observed. While the extent and losses to Bt resistance are still far less than to chemical insecticides used with similar intensity, increasing problems with resistance to Bt, and the lack of remedial strategies when resistance evolves, has highlighted the need to increase efforts to adopt tactics to delay resistance and use Bt more sustainably. As foreshadowed by models and experiments, the cases in which resistance has evolved clearly show the importance of significant and generally deliberately structured refuges, high expression of the Bt toxins relative to the susceptibility of the pests, and the use of pyramided varieties with multiple Bt genes each showing adequate expression. Successfully sustaining the use of Bt will likely require modest government involvement in requiring application of these resistance management tactics.

Insect resistance management in GM crops: Challenges for African farmers

Johann Van den Berg
North-West University, South Africa

The African maize stem borer, Busseola fusca (Lepidoptera: Noctuidae) developed resistance to Bt maize (Cry 1Ab) in South Africa, 7 years after release of Bt maize in the country. Since then resistance spread throughout the maize belt of the country where maize is produced in large scale commercial farming systems. The insect resistance management (IRM) strategy recommended for stem borers is the high-dose/refuge strategy in Bt maize and Bt cotton. For Bt maize, poor compliance to refuge requirements was blamed for resistance development in several cases in other parts of the world as well as South Africa where surveys showed that farmers only started to comply with requirements, 8 years after release of Bt maize. Non-compliance can however not be the only reason for rapid resistance development. Resistance development highlighted huge gaps in knowledge of pest biology (for example migration patterns) and interactions in the wider agro-ecosystem (indigenous host plants/parasitoids). IRM in Africa is faced by challenges unique to farming in subsistence and small scale systems where refuge requirements are unrealistic and difficult to manage and monitor. Furthermore, factors such as seed management practices, gene-flow to maize land races could be contributing factors to resistance development. Alternative IRM strategies such as seed mixtures are more practical but have its own challenges and have not been proven successful yet. While wild host plants of the African boll worm (Helicoverpa armigera) (Lepidoptera: Noctuidae) may contribute to unstructured refugia, this is not the case with any of the maize stem borers.

Controlling corn rootworm with dsRNA: Efficacy, specificity and IRM considerations

William Moar[1], Pamela Bachman[2], Thomas Clark[3], Renata Bolognesi[4], Gerrit Segers[5], Graham Head[6]
[1]Monsanto, U.S.A., [2]Monsanto, U.S.A., [3]Monsanto, U.S.A., [4]Monsanto, U.S.A., [5]Monsanto, U.S.A., [6]Monsanto, U.S.A.

The expression of dsRNA in crop plants, such as maize, to control damaging insect pests such as western corn rootworm (WCR, Diabrotica virgifera virgifera LeConte) represents a new class of insect control traits with a high degree of insect specificity. As with any new plant-expressed insect control trait, the potential for WCR to evolve resistance to dsRNA needs to be considered. This presentation will discuss information regarding pyramiding WCR-active dsRNA with Bt Cry proteins for increased efficacy and decreasing the potential for resistance development while maintaining a relative high degree of specificity in host spectrum

Reconstructing insect invasion routes with genetic tools

Thomas Guillemaud[1], Marc Ciosi[2], Eric Lombaert[3]
[1]INRA of Sophia Antipolis, France, [2]INRA of Sophia Antipolis, France, [3]INRA of Sophia Antipolis, France

Insect invasion biology and agriculture are intimately related because many agricultural insect pests are recent invaders. In this paper we propose that reconstruction of invasion routes with population genetics-based methods can address fundamental questions in ecology and practical aspects of insect pest management. We briefly present the methods of invasion routes reconstruction and describe the main results recently obtained. In particular, we focus on a scenario ? the bridgehead invasion scenario ?, which had been overlooked until recently. We show that this scenario, in which an invasive population is the source of other invasive populations, is evolutionarily parsimonious and may have played a crucial role in insect invasion biology.

Population genetics and disease ecology of mosquito species in Galapagos

Arnaud Bataille[1], Andrew A. Cunningham[2], Simon J. Goodman[3]

[1]Zoological Society of London and University of Leeds, United Kingdom, [2]Zoological Society of London , United Kingdom, [3]University of Leeds, UK

The introduction of new pathogens and disease vectors has been recognized as a major threat to Galapagos Island biodiversity. Here I focus on mosquito species of the Galapagos archipelago, using population genetic and phylogenetic data to understand their historical and current population dynamics. I show that two mosquito species found in the archipelago have very different historical and contemporary evolutionary histories: one species, Aedes taeniorhynchus, naturally colonized the archipelago 200,000yrs ago and is now found widely in the islands, having adapted and spread to a range of different habitats. It has also changed its feeding-behaviour and now frequently feeds on reptiles in addition to mammals, unlike the continental progenitor populations. These properties potentially make Aedes taeniorhynchus a key bridge-vector in the archipelago for any new invading mosquito borne diseases. In contrast, I show that Culex quinquefasciatus, a major vector of diseases such as West Nile virus and avian malaria, has been introduced on multiple occasions since 1985 via human transportation networks and that its distribution and movement in the archipelago depend greatly on human activities. These two species might play an important role in the introduction and spread of new diseases in the Galapagos archipelago.

Outbreeding depression and reluctant virgin oviposition in Californian populations of the bean thrips, *Caliothrips fasciatus* (Pergande) (Thysanoptera: Thripidae), reduce its invasive potential

Paul Rugman-Jones[1], Mark Hoddle[2], Richard Stouthamer[3]

[1]University of California Riverside, U.S.A., [2]University of California Riverside, U.S.A., [3]University of California Riverside, U.S.A.

Bean thrips, Caliothrips fasciatus, is native to western North America. Once considered a pest of several crops in its native area, its pest status has waned over recent decades. However, due to its habit of aggregating in the navel of navel oranges, bean thrips remains economically important because some countries importing oranges from California have designated it a quarantine pest. That said, despite continued propagule pressure, bean thrips has never established outside North America. Using mitochondrial DNA we examined variation among Californian populations of C. fasciatus and found potential evidence of two cryptic species; a common widespread form (B), and a rarer form (A) with a very limited distribution. Form B showed strong phylogeographic structure and inter-population crossing experiments between three geographically isolated populations of form B revealed evidence of substantial outbreeding depression between these populations. A low frequency of offspring production by hetero-population pairs was evidence of pre-mating isolation, while post-mating isolation in this haplodiploid species was also evident in the elevated mortality of fertilized eggs in successful hetero-population crosses. One surprising finding was the total lack of offspring production by virgin females when isolated individually. However, virgin females did produce sons in the presence of other virgin females. These factors, acting alone or in concert, are likely to adversely affect the invasion potential of C. fasciatus and may explain why it has been unable to establish outside of its native range, from small founding populations accidentally exported in Californian navel oranges.

Invasion genetics of the western flower thrips in China: Evidence for genetic bottleneck, hybridization and bridgehead effect

Xlan-Ming Yang[1], Jing-Tao Sun[2], Xiao-Feng Xue[3], Xiao-Yue Hong[4]

[1]Nanjing Agricultural University, China, [2]Nanjing Agricultural University, China, [3]Nanjing Agricultural University, China, [4]Nanjing Agricultural University, China

The western flower thrips, Frankliniella occidentalis (Pergande), is an invasive species and the most economically important pest within the insect order Thysanoptera. F. occidentalis, which is endemic to North America, was initially detected in Kunming in southwestern China in 2000 and since then it has rapidly invaded several other localities in China where it has greatly damaged greenhouse vegetables and ornamental crops. Using the mitochondrial COI gene and 10 microsatellites, eight of which were newly isolated and are highly polymorphic, we investigated the genetic structure and the routes of range expansion of 14 F. occidentalis populations in China. Both the mitochondrial and microsatellite data revealed that the genetic diversity of F. occidentalis of the Chinese populations is lower than that in its native range. Two previously reported cryptic species (or ecotypes) were found in the study. The divergence in the mitochondrial COI of two Chinese cryptic species (or ecotypes) was about 3.3% but they cannot be distinguished by nuclear markers. Hybridization might produce such substantial mitochondrial-nuclear discordance. Furthermore, we found low genetic differentiation (global FST = 0.043, P < 0.001) among all the populations and strong evidence for gene flow, especially from the three southwestern populations (Baoshan, Dali and Kunming) to the other Chinese populations. The directional gene flow was further supported by the higher genetic diversity of these three southwestern populations. Thus, quarantine and management of F. occidentalis should focus on preventing it from spreading from the putative source populations to other parts of China.

Putative source and social form of the red imported fire ant, *Solenopsis invicta* disclosed by molecular markers in China

Xingfu Jiang[1], Jingguo Shao[2], Lizhi Luo[3], Lei Zhang[4]

[1]Chinese Academy of Agricultural Sciences, China, [2]Institute of Plant Protection, Chinese Academy of Agricultural Sciences, China, [3]Chinese Academy of Agricultural Sciences, China, [4]Chinese Academy of Agricultural Sciences, China

The red imported fire ant (RIFA), Solenopsis invicta, a damaging invasive pest, was first introduced to mainland China in 2005 in Guangdong province, spreading to Guangxi, Fujian and Hunan province thereafter. Six microsatellite loci were selected to detect genetic diversity among 238 samples from 6 geographical populations of RIFA. 45 alleles were tested in all the loci with the mean allelic number of 7.5 and the efficient allelic number of 18.75. Hardy-Weinberg equilibrium analysis revealed a remarkable genetic equilibrium and an obvious diversity at most of the loci in 6 geographical populations. The average polymorphism information content varied between 0.0000-0.8011. The average observed and expected heterozygosity ranged from 0.5740 to 0.7778 and from 0.6104 to 0.7068, respectively. FST value of different locus varied from 0.0595 to 0.1304, with the average value of 0.0961, indicating though high levels of intraspecific genetic variation existed, the interspecific genetic differentiation were moderate. Cluster analysis conducted by UPMGA separated 16 RIFA subpopulations in China into 4 categories, Guangxi, Yuexi and Fujian populations were firstly grouped, indicates they are might from the same source region. Zhusanjiao populations were separated into 2 categories, indicating another two separated source regions. Taiwan population became a separate unique group, indicating a low possibility of introduction to mainland China. Both monogyne and polygyne were presented in mainland China using Gp-9Bb alleles with multiplex PCR, but with polygynes dominant. The ratio of polygynous to monogynous colonies was 97: 23 in the 120 fire ant colonies collected, but differed as location varied.

Distinct invasion pattern of an alien whitefly correlated with different dominant haplotypes

Dong Chu[1], Xianchun Li[2], Youjun Zhang[3], Fanghao Wan[4]

[1]Qingdao Agricultural University, China, [2]University of Arizona, Tucson, U.S.A., [3]Chinese Academy of Agricultural, China, [4]Chinese Academy of Agricultural Sciences, China

It is poorly understood why particular populations of an alien species can establish and become invasive in an introduced region, whereas others do not. We show that different invasion patterns of an alien whitefly Bemisia tabaci biotype Q (also known as "Mediterranean species") in China and USA were associated with introduced cryptic haplotypes. Our long-term field survey conducted in Shandong, China and Arizona, USA in cotton and multiple other crops showed that B. tabaci biotype Q can displace well-established population of biotype B in China while biotype Q can only be detected in greenhouse ecosystems in the USA during the past several years. Based on molecular method and laboratory experiments, we revealed that the dominant haplotypes of biotype Q introduced in China and in USA differ in many biological traits, which may partially help explain the difference in its competition ability and thus in its invasiveness in introduced regions.

Using haplotypes to map fall armyworm (*Spodoptera frugiperda*) migration pathways in the United States

Rodney Nagoshi[1], Shelby Fleischer[2], Robert Meagher[3], John Westbrook[4]
[1]USDA-ARS, U.S.A., [2]The Pennsylvania State University, U.S.A., [3]USDA-ARS, U.S.A., [4]USDA-ARS, U.S.A.

Spodoptera frugiperda (J.E. Smith; Lepidoptera: Noctuidae) or fall armyworm is an important agricultural pest of a number of crops in the western hemisphere. Two morphologically identical host strains of fall armyworm exist, the rice-strain and corn-strain, with the latter inflicting substantial economic losses in corn in both North and South America. Fall armyworm does not survive severe winters so the infestations affecting North America originate from migrants that overwinter in Florida and Texas. A haplotype method was developed that could distinguish the corn-strain populations from these two locations and was used to delineate the migratory pathways. The results from five years of surveys will be described. We also examined the population movements of fall armyworm in the Caribbean and the magnitude of genetic interactions, if any, with populations from North, South, and Central America. The results indicate limited interactions between Puerto Rico fall armyworm and those from Brazil or Texas, but the potential for significant exchanges with populations in Florida. A better understanding of fall armyworm populations and their movement is critical for the development of strategies to predict infestation levels and eventually control this economically important pest in the United States.

Estimation of emigration from a forest insect outbreak using population genetic tools

Anna Cassel Lundhagen[1], Cecilia Ronnas[2], Andrea Battisti[3], Johan Wallen[4], Stig Larsson[5]

[1]Swedish University of Agricultural Sciences, Sweden, [2]Swedish University of Agricultural Sciences, Sweden, [3]Universita di Padova, Italy, [4]Swedish University of Agricultural Sciences, Sweden, [5]Swedish University of Agricultural Sciences, Sweden

Population densities vary over time, and some species occasionally increase to very high numbers, for example during outbreaks. In such situations populations are expected to expand into new areas due to density-dependent dispersal and sometimes even result in range expansion. We investigated if an outbreak in a local population of the northern pine processionary moth Thaumetopoea pinivora had resulted in establishment of populations in suitable habitats outside of the outbreak area. Six small populations were found that could potentially have originated from the outbreak area. Using data from 12 microsatellite markers and a variety of population genetic analyses we could conclude that these populations did not originate from the recent outbreak. Genetic variability was not reduced in these small, isolated populations and there were several unique alleles, indicating instead a different population history. In addition, there was apparent genetic isolation by geographic distance, implying that despite the high density of the outbreak population, significant gene flow has not occurred.

On the potential of population genetics to refine scales for locust management

Marie-Pierre Chapuis[1], Karine Berthier[2], Julie-Anne Popple[3], Gregory Sword[4]
[1]CIRAD, France, [2]INRA, France, [3]University of Sydney, Australia, [4]Texas A&M University, United States Minor Outlying Islands

Linking demographic and genetic dispersal measures is of fundamental importance for movement ecology and evolution. However, such integration can be difficult, particularly for highly fecund species that are often the target of management decisions guided by an understanding of population movement. Here, we present an example of how the influence of large population sizes can preclude genetic approaches from assessing demographic population structuring, even at a continental scale. The Australian plague locust, Chortoicetes terminifera, is a significant pest, with populations on the eastern and western sides of Australia having been monitored and managed independently to date. We used microsatellites to assess genetic variation in 12 C. terminifera population samples separated by up to 3000 km. Traditional summary statistics indicated high levels of genetic diversity and a surprising lack of population structure across the entire range. An approximate Bayesian computation treatment indicated that levels of genetic diversity in C. terminifera corresponded to effective population sizes conservatively composed of tens of thousands to several million individuals. We used these estimates and computer simulations to estimate the minimum rate of dispersal that could account for the observed range-wide genetic homogeneity. The rate of dispersal between both sides of the Australian continent could be several orders of

Understanding dispersal and movement of *Aphis glycines* to improve durability of aphid resistant soybean

Andrew Michel[1], M. A. R. Mian[2], Raman Bansal[3], Jacob Wenger[4], Lucia Orantes[5]

[1]OARDC, The Ohio State University, U.S.A., [2]OARDC, The Ohio State University, U.S.A., [3]OARDC, The Ohio State University, U.S.A., [4]OARDC, The Ohio State University, U.S.A., [5]OARDC, The Ohio State University, U.S.A.

The soybean aphid, Aphis glycines, has become the most important soybean insect pest in the North Central US region since its first discovery in 2000. By screening thousands of soybean varieties, several have been discovered with host-plant resistance to the soybean aphid. Currently there are 4 formally described resistance genes (termed Rag for Resistance to Aphis glycines), with Rag1 being commercially released in 2010. However, soybean aphid populations have been found that can overcome Rag-based resistance, despite the lack of intense selection pressure. Aphids that have overcome resistance offered by Rag plants threatens the efficacy and sustainability of host-plant resistance as an aphid management tactic. Therefore, research is needed to describe both the genetic mechanisms for soybean aphid adaptation and the potential for this adaptive genetic variation to spread across the soybean growing region. Data will be presented on progress towards identifying the genetic mechanisms, evaluating signatures of selection on these traits in natural populations, molecular profiling of soybean aphids collected on different Rag soybeans, and defining the influence of host alternation on population genetic structure. Implementation of this data towards the development of strategies that delay the spread of adaptation and extend the durability of host plant resistance will also be discussed.

Genome scans for adaptation to transgenic Bt maize

Nicholas Miller[1], Bruce Hibbard[2], Thomas Sappington[3]
[1]University of Nebraska-Lincoln, U.S.A., [2]University of Nebraska-Lincoln, U.S.A., [3]University of Nebraska-Lincoln, U.S.A.

Genome scanning involves surveying large numbers of markers in populations subject to diversifying selection. The goal is to identify the small minority of markers at which allele frequencies are diverging between populations more rapidly than would be expected as a result of genetic drift. These markers may then be considered as potentially located in regions of the genome where selection is acting. Although genome scanning has proven problematic when studying natural populations, it has considerable promise as a tool for studying laboratory populations that have been subjected to selection regimes. Here we consider the case of laboratory populations of the western corn rootworm, Diabrotica virgifera virgifera that have been maintained on transgenic maize varieties expressing insecticidal Bt toxins versus populations maintained on non-transgenic isolines. A simulation approach is used to investigate the density of genetic markers required to achieve reasonable power to detect selection.

Paratransgenic symbionts that express targeted toxins in the termite gut

Claudia Husseneder[1], Chinmay Tikhe[2], Jennifer Delatte Donaldson[3]

[1]Louisiana State University Agricultural Center, U.S.A., [2]Louisiana State University Agricultural Center, U.S.A., [3]Louisiana State University Agricultural Center, U.S.A.

Formosan Subterranean Termites (FSTs). FST workers harbor a complex microbial community of protozoa and bacteria in their hindguts on which they depend for survival. Therefore, this microbial community can be exploited as a novel, pesticide-free tool for termite control. We have shown that antimicrobial peptides (e.g., Hecate) kill the protozoa in the-termite gut. Termites starve after the loss of their gut protozoa, since protozoa are necessary for cellulose digestion. The addition of a ligand, which binds the antimicrobial peptide to the protozoa, increased the specificity and efficiency of the antimicrobial peptide against termite gut protozoa. In this study, we engineered termite gut bacteria as "Trojan Horses" to express antimicrobial peptides in the termite gut and spread them among colony members to eliminate the colony. To achieve this goal we (1) cultured bacteria from the FST hindgut and identified them using 16S rRNA gene sequencing, (2) selected bacteria with high tolerance to Hecate and/or ligand-Hecate in bioassays, (3) engineered bacteria to express Hecate or ligand-Hecate via plasmid transformation and/or integration into the chromosome using transposons, and (4) tested the engineered bacteria for their ability to kill protozoa in vitro (protozoa culture) and in vivo (feeding to termites, termite mortality assays).

Gene flow and neighborhood area in European corn borer (Lepidoptera: Crambidae) in the U.S., and implications for insect resistance management

Thomas W. Sappington[1], Kyung Seok Kim[2], Jing Sun[3], Shelby Fleischer[4]

[1]USDA-Agricultural Research Service, U.S.A., [2]Seoul National University, Republic of Korea, [3]Iowa State University, U.S.A., [4]Pennsylvania State University, U.S.A.

The European corn borer (Ostrinia nubilalis) is a major invasive pest of corn in the US and is the main target of transgenic Bt-corn expressing Cry1Ab or Cry1F toxins. Because of the high adoption of Bt-corn, there is intense selection pressure for resistance, and farmers must plant a nonBt refuge as part of an insect resistance management (IRM) plan. Effectiveness of IRM depends on gene flow among corn borer populations. We have used population genetics approaches to estimate gene flow, but interpretation of results has been complicated by the history of invasion which can affect genetic signals. Interpretaions are also complicated in North America by the presence of partially reproductively isolated races with different pheromone systems. Many areas in the northeastern U.S. are characterized by high topographic relief, which may serve to isolate some populations through barriers to dispersal, affecting gene flow and the potential for resistance evolution. We report preliminary gene flow estimates based on microsatellite and SNP markers, both within and between pheromone races in areas where topography may affect dispersal. We found that topography may play a role in limiting dispersal in the E pheromone race, but not in the more common Z race. Although gene flow in the E race is high, it is more restricted than in the Z race. We used an independent demographic estimate of population density to calculate Wright's neighborhood area. The results suggest that >13% of moths disperse >12 km/generation before ovipositing. Overall, our results indicate effective dispersal over long distances.

Genetic differentiation and gene flow among different geographical populations of *Ostrinia furnacalis* in China based on multiple molecular markers

Jing Li[1], Zhenying Wang[2], Sergine Ponsard[3], Denis Bourguet[4], Kanglai He[5]

[1]Chinese Academy of Agricultural Sciences, China, [2]Institute of Plant Protection, Chinese Academy of Agricultural Sciences, Beijing 100193, China, [3]Toulouse III University, France, [4]Campus International de Baillarguet , France, [5]Chinese Academy of Agricultural Sciences, China

Investigations on genetic differentiation and gene flow among geographic populations of the Ostrinia furnacalis from China were detected by using both microsatellite and mitochondrial DNA markers.The results showed high genetic diversity in mtDNA genes of O. furnacalis populations. Practical microsatellite system for O. furnacalis population studies was developed based on microsatellite loci reported in O. nubilalis. Six polymorphic SSR loci were estimated by GeneScan sequencing technology. Two loci showed deviation from Hardy-Weinberg equilibrium (P-value < 0.05). The genotypic data showed no significant linkage disequilibrium between pairs of loci (P > 0.05). Topological structure of the phylogenic tree demonstrated no geographic clustering was observed. There was low correlation between Fst / (1 - Fst) and geographical distance (r = 0.135, P = 0.0025). Analysis of molecular variance results revealed that most of the genetic variation was within populations; less variation was detected among populations within each corn region, which suggested no obvious genetic differentiation among these corn regions. The degree of genetic divergence and gene flow varied within different corn regions. The relatively lowest Fst and highest degree of gene flow (Nm) was among populations in Huanghuaihai Summer Corn Region, while there detected significant genetic differentiation and relatively low Nm among populations in both North Spring Corn Region and Southeast Hilly Corn Region. In addition, results of Tajima's D and Fu's Fs neutrality tests implied that there might not be a population expansion in recent time and the Asian corn borer populations was at demographic equilibrium.

Pattern of dispersal and gene flow of cotton boll weevil in North America

Kyung Seok Kim[1], Thomas W. Sappington[2]
[1]Seoul University, Republic of Korea, [2]United States Department of Agriculture-Agricultural Research Service, CICGRU, U.S.A.

The boll weevil (Anthonomus grandis Boheman) is an invasive insect pest of cotton that underwent a well documented range expansion across the southeastern U.S. from Mexico beginning about 120 years ago. The magnitude and pattern of genetic differentiation among boll weevil populations from North America across eight U.S. states and northern Mexico were evaluated using microsatellite loci analysis. Measures of genetic diversity (allelic diversity and heterozygosity) were greater in Southern than Northern populations, and were greater in the west than the east among Northern US populations. Classical F-statistics and Bayesian-based clustering analysis suggested that boll weevil populations were genetically structured across the geographic range sampled. South-Central US populations exhibit classic isolation by distance, indicating genetically stable populations, but evidence suggests that populations within the Eastern and Western regions have not yet reached genetic equilibrium. Gene flow appears to be relatively high among populations within the Eastern region. Population assignment data and estimates of gene flow indicate that migration between locations separated by several hundreds of km is frequent. Several case studies for North American boll weevil populations imply that the database of microsatellite genotypes makes it possible, through population assignment techniques, to identify the most likely geographic source of a boll weevil reintroduced to an eradication zone, which helps action agencies decide the most appropriate mitigation response.

Regional and global population structure of the oriental fruit moth, *Grapholita molesta*

Dominique Mazzi[1], Heather Kirk[2], Marco Torriani[3], Silvia Dorn[4]
[1]ETH Zurich, Switzerland, [2]ETH Zurich, Switzerland, [3]ETH Zurich, Switzerland, [4]ETH Zurich, Switzerland

Invasive pest species have significant impacts on agricultural crop yields. Understanding the population dynamics of invasive species is key to their management, and hence to ensure food security in the face of the increasing pressure on agricultural productivity imposed by the twin challenges of human population growth and climate change. The oriental fruit moth, Grapholita molesta is an economically destructive pest of stone and pome fruit, including peach and apple. From its putative native range in Asia, G. molesta has spread throughout the temperate regions of the world over the past century, and is further expanding its distribution range polewards. We used polymorphic microsatellite markers to examine 1) population genetic structure of G. molesta in a fruit-growing area in Northern Italy, and 2) population genetic structure of G. molesta worldwide. At the regional scale, population structure of G. molesta was relatively low, and could be explained by both active dispersal and passive dispersal via anthropogenic movement of fruit, bins and nursery material. At the global scale, population structure of G. molesta generally reflected continental divisions. There was little evidence for multiple introductions to each continent, or for admixture between populations from different origins, suggesting that area-wide spread via transport of fruits and other materials is a major mechanism of ongoing invasion. Consistent evidence that the spread of G. molesta is aided by trade-related human activities urge for improved community-based control measures, and for more stringent regulations regarding the transport of plant material.

The Molecular Phylogeny and population genetics of the rice grasshopper, *Oxya* genus

Enbo Ma[1], Tao Li[2], Min Zhang[3], Zhumei Ren[4], Yang Zhong[5], Jianzhen Zhang[6]

[1]Shanxi University, China, [2]Shanxi University, China, China, [3]Shanxi University, China, [4]Shanxi University, China, [5]Tibet University, China, [6]Shanxi University, China

The grasshoppers of the genus Oxya are well known to damage rice. We investigated the phylogenetic relationship of Oxya genus from 91 individuals of nine Oxya species by using mitochondrial cytochrome b gene sequence analysis. The results showed that the nine Oxya species formed four well-supported clades. Seven populations were sampled to investigate the genetic differentiation among grasshopper populations with different hosts (i.e. wild vs. cultivated rice). We found significant genetic differentiation between groups collected from different hosts. The results suggested that the anthropogenic activity in cultivated rice fields could have played an important role in shaping the genetic structure of O. japonica. 100 individuals of Oxya japonica were analyzed by using COI DNA sequences collected from four Southeast Asian countries. The results showed that high genetic variance among groups were found which indicating a relatively strong geographic structure. All clades diverged from a common ancestor, and deep divergences were happened related to specific geologic events. The expansion times of southwest China and north Philippines groups were 92820 years ago and 70940 years ago, respectively. Oxya intricata of 12 populations were collected from four Southeast Asian countries by using mitochondrial DNA COI sequences and AFLP. Phylogenetic analysis and TCS indicated three deep monophyletic clades that approximately corresponded to three geographical regions separated by high mountains and a deep strait. In conclusion, the past geological events and climatic fluctuations were important factors on the phylogeographical structure and genetic patterns of O. intricata in Southeast Asia.

Planthoppers threatening rice in Asia again? Why?

K.L. Heong
International Rice Research Institute, Philippines

In the last 5 years rice planthoppers (Nilaparvata lugens and Sogatella furcifera) have become the most damaging pests of rice. From 2008 Thailand's rice bowl has suffered continuous outbreaks for 9 consecutive seasons. In 2010 rice production lost 1.1 million tons of paddy and this year another loss of about 1 million tons is expected. Similarly Indonesia is suffering the same threats and had lost about a million tons in 2011. Smaller patches of outbreaks occur in India, Myanmar, Bangladesh, Philippines and India while China continues to lose about 1 million tons a year. Besides economic loss, hundreds of farmers suffer crop failures, falling in debts and poverty, pesticide poisoning and even suicides. Planthoppers are induced secondary pests that normally under natural control. Outbreaks are symptoms of unsustainable practices that destroy vital ecosystem services triggering exponential growth. Although abnormal weather like droughts and floods can trigger outbreaks, the most consistent factor in Asia seems to be insecticide misuse. The presentation describes the economic and social impacts of the outbreaks and looks at 3 ecological principles and the management strategies that might have contributed. It will discuss the need to take a broader view to consider social, marketing, structural and policy issues beyond the development technological fixes in order to prevent future outbreaks.

Occurrence and migration of *Nilaparvata lugens* in the Vietnamese Mekong Delta

Akira Otuka[1], Toshihiro Sakamoto[2], Ho Van Chien[3], Masaya Matsumura[4]

[1]NARO/Kyushu Okinawa Agricultural Research Center, Japan, [2]National Institute for Agro-Environmental Sciences, Japan, [3]Southern Region Plant Protection Center, Vietnam, [4]NARO/Kyushu Okinawa Agricultural Research Center, Japan

The brown planthopper, Nilaparvata lugens, is one of the most important insect pests of rice in the Vietnamese Mekong Delta. Virus diseases transmitted by the insect, for example, severely spread in the delta in 2006 and the government stopped rice exporting for their food security. The level of insecticide resistance of the N. lugens populations in this region is much higher than that of populations in the northern Vietnam. Therefore, their migration in the delta is a chief concern, but not fully understood so far. To access a whole image of occurrence and migration of N. lugens in the delta, a new technique was employed by using one material and two methods: a dense light trap monitoring data, analytical image of paddy fields from the MODIS satellite and trajectory analysis to suggest the insects' movements. The monitoring data in each province indicated clear seasonal and generational occurrence patterns. Generational occurrence peaks with an interval of about 30 days indicated that the population consisted mainly of insects locally multiplied. Additionally, the peaks of the paddy area at harvesting time estimated by the remote sensing corresponded well to that of the insect occurrence. This fact suggested N. lugens's dispersion and migration occurred in synchronization with rice harvesting. Finally, the distance of N. lugens migration in the delta was estimated by the new technique and found to be about 100 km. The distance is less than one-tenth of that of the long-migratory East Asian population.

The return migration of rice planthoppers: Gaps in the loop

Baoping Zhai[1], Dabing Zheng[2], Haibo Yang[3], Guo Zhang[4], Xiao CHEN[5]

[1]Nanjing Agricultural University, China, [2]Nanjing Agricultural University, China, [3]Nanjing Agricultural University, China, [4]Nanjing Agricultural University, China, [5]Nanjing Agricultural University, China

The rice planthoppers (RPH) migrate regularly northward in spring and summer and southward in autumn, that perform a perfect loop between Indo-China Peninsula and the mainland of China. However, some gaps in the loop were noticed during a field survey in northern Viet Nam in November of 2009. Rice is the only food for RPH, but there was no rice planting in mid and north Viet Nam during a 3-months interval between the two cropping seasons (summer-autumn rice and winter-spring rice). Although the ratoon rice and the seedlings of the falling grain may provide foods and habitats for the returned hoppers, but very few RPH could be seen on them during our field surveys in 2011 and 2012. Also, simulating the flying pathways of the emigrants illustrated that it would be impossible for the RPH taking off from Mekong delta and other southern provinces to enter into mid and north Viet Nam. Even for the emigrants from Quang Nam and Quang Ngai, there would be also very few opportunity (< 20%) to arrive in mid Viet Nam. So the problems arise. How will the returned RPH populations survive with no food in so large area and so long time? How do the source populations of RPH rebuild in the winter-spring rice fields? Especially, how dose the southern rice black-streaked dwarf virus complete its infection cycles? And, is the pied piper playing his magic pipe? More detailed studies will be needed to reveal the mystery of the returned hoppers.

How are *Nilaparvata lugens* in East Asia adapted for long-distance migration: Differences in a few migration-related characters between the planthoppers in the tropics and temperate regions?

Takashi Wada
NARO Kyushu Okinawa Agricultural Research Center, Japan

Accumulated information for the last 40 years has revealed that Nilaparvata lugens in East Asia make annual long-distance migration with assist of the wind system: northward movement in early summer and probable return migration in autumn. We compared few migration-related characters of N. lugens collected at various locations in East Asia and tropical Southeast Asia to identify their possible adaptation for migration. Macropters in East Asia had longer pre-ovipositional periods (7.6 days) compared to tropical macropters (4.7 days), which is presumably beneficial for pre-reproductive migration. Macropters maximized their feeding at the first few days after adult moult. This post-eclosion feeding markedly increased starvation tolerance in East Asia macropters relative to tropical ones: the tolerance of macropters after 76 hr. feeding increased 2.5 and 1.6 fold compared to unfed ones, respectively. Thus, East Asian macropters are 1.6 fold more resistance to starvation than tropical ones with the same conditions after feeding. These findings suggest a difference in the allocation of resources between East Asian and tropical N. lugens. In East Asian macropters, feeding was maximized at the first 2 days and this energy intake was invested in reserves. Feeding reduction on day 3 approximately coincide with maximum starvation tolerance, suggesting the timing of take-off from paddies. On the other hand, feeding by tropical macropters was maximized in the first 3 days. Much of this energy intake was probably invested in vitellogenesis. I further discuss how East Asia N. lugens has evolved in spite of the great disadvantage of prolonged oviposition.

Genetic background of the migratory capability of the brown planthopper, *Nilaparvata lugens*

Sumio Tojo[1], Sunao Morooka[2]

[1]Saga University, Japan, [2]Saga Women's Junior College, Japan

We generated four pure lines of the brown planhopper, Nilaparvata lugens, each showing one predominant wing form and body color, through the successive selection of emergent adults with these characteristics from a group of specimens collected in the fields and reared at high density: blackish short-winged (brachypterous) (BS), blackish long-winged (macropterous) (BL), yellowish short-winged (YS) and yellowish long-winged (YL) Repeating a series of crossing experiments in every possible combination with these four pure lines these 20 years, we propose here a two-major gene model for wing form regulation: one gene locus on an autosome and another locus on X sex chromosome, assuming short-wing inducing gene and long-wing inducing gene as allele, each additively functioning to induce the target wing form. We also show that a similar two-major gene model for body color regulation, assuming blackish body color inducing gene and yellowish body color inducing gene as allele. These models explaine well all of the results obtained by crossing experiments. The four lines differ also in several life-histry traits: the the developmental time is in the order of BS < BL= YS < YL; pre-obiposion period, in the order BS < YS < BL = YL, and also in egg period, longevity and fecundity, suggesting that the genes related to regulation of wing form and body color expression are also involved in the regulation of life histry traits. The pleiotrophic effects of these genes would adapt the hoppers to survive in various circumstances which they would encounter after migration.

Regional surveillance of rice plantoppers in Asian rice area

Yoo Han Song
Gyeongsang National University, Republic of Korea

The regional rice planthopper surveillance network had been established since April 2011 with the participation of Vietnam (South and North), Cambodia, Thailand, Philippines, Indonesia, Bangladesh, Laos, and Nepal. Through the surveillance network, the rice planthoppers and transmitted virus diseases can be intensively monitored then shared the information along the participated region. The surveillance activities include daily light trap catch and weekly yellow sticky trap sampling in the monitoring rice fields. This activities are the first internationally organized attempts to monitor actual field population, which have normally been ignored. The field monitoring data can be used to facilitate the prediction of adults emigration and to understand how each of the rice region connected to the others in terms of the rice planthopper occurrence.

On-farm management of rice varieties for increased efficiency in planthopper population regulation

Finbarr G. Horgan
International Rice Research Institute, Philippines

Planthoppers have reemerged as a considerable threat to rice production in irrigated rice-growing regions throughout Asia. Evidence suggests that planthopper populations are sensitive to perturbations of predator and parasitoid densities and efficiencies. The most popular approaches for reducing planthopper densities have included planting of resistant varieties and the use of chemical insecticides; however, evidence suggests that the efficiency and durability of resistant varieties are depleted under the influence of insecticides. Furthermore, the use of high levels of nitrogen fertilizers has been shown to reduce resistance in some plants. This talk examine the interactions between host-plant resistance, chemical fertilizers, and insecticides in determining the efficiency of planthopper population increase and regulation in rice paddies. It proposes a system of resistance management for increased durability of non-renewable resistance genes.

Plant penetration behavior of the rice sap-sucking Homopterans on susceptible and resistant rice varieties using DC-EPG system

Bo Yoon Seo[1], Jin Kyo Jung[2], Youn-Hee Kwon[3], Gil-Hah Kim[4]

[1]RDA, Republic of Korea, [2]RDA, Republic of Korea, [3]Chungbuk National University, Republic of Korea, [4]Chungbuk National University, Republic of Korea

The stylet penetration behavior of four rice sap-sucking homopteran pests, Nilaparvata lugens, Sogatella fruciferra, Laodelphax striatellus, and Nephotettix cincticeps in rice plants (Oryza sativa) was evaluated by using an electrical penetration graph (EPG). We classified the EPG waveforms of planthopper group into seven different patterns, np, N1, N2, N3, N4-a, N4-b, and N5, according to their shapes, voltage amplitudes, voltage levels, and frequencies. The N4-b pattern was always preceded by N3 and N4-a, in that order. Continuous honeydew excretion only occurred during the N4-b period, and the plant sap flowed out of the severed stylets in the N4-b period consisted of sucrose mainly. On the other hand, we classified the EPG waveforms of the green rice leafhopper, N. cincticeps into seven different patterns, Nc1, Nc2, Nc3, Nc4, Nc5, Nc6, and Nc7. The Nc6 pattern was always preceded by the Nc5 pattern. Honeydew was periodically excreted only in the Nc6 pattern. The N4-b pattern of the planthopper group and the Nc6 pattern of the leafhopper were carefully considered as a phloem sap feeding behavior. However, the planthopper group and the leafhopper hardly showed the phloem sap feeding pattern on resistant rice varieties during an EPG-recording. In addition, the duration of the phloem sap feeding patterns was highly decreased on resistant rice varieties relative to susceptible ones. These results suggest that the phloem sap feeding patterns (N4-b and NC6) are an important parameter to determine resistance of rice plant against rice sap-sucking homopteran pests.

Rice volatile signals are important regulators of rice-brown planthopper interactions

Yonggen Lou
Zhejiang University, China

In response to insect attack, plants release complex blends of volatile compounds. These volatiles serve as foraging cues for herbivores, predators and parasitoids, leading to plant-mediated interactions within and between trophic levels. Hence, plant volatiles may be important determinants of insect community composition. To test this we created rice lines that are impaired in the emission of two major signals, S-linalool and (E)-β-caryophyllene. We found that inducible S-linalool attracted predators and parasitoids as well as chewing herbivores, but repelled the rice brown planthopper Nilaparvata lugens, a major pest. The constitutively produced (E)-β-caryophyllene on the other hand attracted both parasitoids and planthoppers, resulting in an increased herbivore load. Thus, silencing either signal resulted in specific insect assemblages, a finding that highlights the importance of plant volatiles in determining population density of the rice brown planthopper and insect community structures. Moreover, the results imply that the manipulation of volatile emissions in crops has great potential for the control pest populations.

Exploring the factors underlying variation in brown planthopper-rice interactions

Yolanda H. Chen
University of Vermont, U.S.A.

Populations of the brown planthopper, Nilaparvata lugens, appear to vary both spatially and temporally in their performance on resistant rice varieties. Given that breeding for host plant resistance has been a central focus for planthopper management in rice, it is critically important to understand the factors that appear to underlie geographic variation in planthopper populations, and how they may change over time in response to resistant rice varieties. Here, we present two datasets: 1) The first examines population genetic structure of N. lugens throughout Asia, and 2) the second is a full factorial study examining how the reared host plant, exposed host plant, number of generations, and yeast-like endosymbionts may influence planthopper nymphal development and amino acid composition. We found a high level of population genetic structure throughout Asia, suggesting that planthoppers tend to exhibit a high level of inbreeding. Nymphal development was strongly influenced by a four-way interaction between the exposed rice variety, natal rice variety, number of reared generations, and YLS presence. Aposymbiotic planthoppers reared for more generations had a higher proportional concentration of rare amino acids than those reared for 8 generations, indicating that the selected planthopper populations appeared to improve their ability to acquire rare amino acids. Therefore, the change in amino acid composition of planthoppers suggests an underlying change in protein expression or amino acid metabolism over time.

Recent situation of rice viruses transmitted by planthoppers in Southeast Asia

Il-Ryong Choi
International Rice Research Institute, Philippines

Rice viruses such rice grassy stunt virus (RGSV), rice ragged stunt virus (RRSV), and Southern rice black-streaked dwarf virus (SRBSDV) transmitted by planthoppers gave serious damages to rice production in Southeast Asian countries. These viruses can independently infect rice plants. However, incidences of mixed infection of rice with RGSV and RRSV both transmitted by brown planthoppers (BPH) were often observed in countries like Vietnam and Indonesia. Also, mixed-infection of rice with SRBSDV, which is transmitted by white-backed planthoppers, and RRSV was also frequently observed in Northern and central parts of Vietnam. In fields, in addition to cultivated rice plants, weeds such as Echinochloa crus-galli and wild rice species such as Oryza rufipogon were found to serve as a reservoir for RGSV and RRSV. In Southern Vietnam, overlaps among cropping seasons across the rice cultivation areas, and overlaps between the BPH migration patterns and rice cropping patterns might have been the major cause of the outbreaks. In addition, predominant cultivation of rice varieties which are susceptible to BPH and the viruses might have facilitated the outbreaks. Examination of transmission characteristics of the viruses by BPH indicated that the transmission can be completed in a very short time (less than 20 min) in Southern Vietnam. These facts should be considered to establish a more effective management strategy for rice viruses transmitted by planthoppers in Southeast Asian countries.

Imidacloprid resistance in the brown planthopper: Different stories in lab and field

Zewen Liu[1], Zhiping Ding[2], Xiangkun Meng[3], Beina Guo[4], Feng Jiang[5]

[1]Nanjing Agricultural University, China, [2]Nanjing Agricultural University, China, [3]Nanjing Agricultural University, China, [4]Nanjing Agricultural University, China, [5]Nanjing Agricultural University, China

Neonicotinoid insecticides are selective agonists of insect nicotinic acetylcholine receptors (nAChRs) and are used extensively to control a variety of insect pest species. The brown planthopper (Nilaparvata lugens), an insect pest of rice crops throughout Asia, is an important target species for control with neonicotinoid insecticides such as imidacloprid. Previous studies identified a point mutation (Y151S) in two different nAChR subunits (Nlα1 and Nlα3) from a selected lab strain of N. lugens with high resistance to imidacloprid. In heterologous expression system, such mutation had been confirmed to contribute to imidacloprid resistance in N. lugens as the target insensitivity. Interestingly, although studies are now underway to examine the prevalence of the Y151S mutation in field populations, to date there is no evidence to indicate that this laboratory-selected target-site mutation is responsible for resistance in field populations of N. lugens. When screening the changes in detoxification enzymes in field populations with different levels of imidacloprid resistance (ratio=17-82 fold), a P450 monooxygenase gene, CYP6AY1, was found high expressed in all field populations, with 4.3-9.0 fold increase in mRNA levels. By expressing in E. coli cells, CYP6AY1 was found to metabolize imidacloprid with high activity. When CYP6AY1 mRNA levels were reduced by RNA interference, imidacloprid resistance was lowered. In conclusion, the biochemical mechanism based on P450 monooxygenase activity increase might be the main mechanism for imidacloprid resistance in field populations, when the target site mutation is not prevalent at present.

Species and area specific development of insecticide resistance in Asian rice planthoppers

Masaya Matsumura[1], Sachiyo Sanada-Morimura[2], Akira Otuka[3]

[1]NARO Kyushu Okinawa Agricultural Research Center, Japan, [2]NARO Kyushu Okinawa Agricultural Research Center, Japan, [3]NARO Kyushu Okinawa Agricultural Research Center, Japan

Outbreaks of the brown planthopper (BPH), Nilaparvata lugens (Stal) and the whitebacked planthopper (WBPH), Sogatella furcifera (Horvath) have occurred in East Asia and Indochina since 2005. Outbreaks of the small brown planthopper (SBPH), Laodelphax striatellus (Fallen) has also occurred in China and Japan since mid-2000s. These outbreaks are closely related to the development of insecticide resistance of the populations in these regions. The insecticide susceptibility of the three planthoppers in Asian countries was determined and compared from 2006-2010 by topical application method. A species-specific change in the insecticide susceptibility was found in BPH and WBPH: imidacloprid resistance in BPH and fipronil resistance in WBPH. Resistance to imidacloprid has developed only in BPH in East Asia (Japan, China and Taiwan) and Vietnam, but not in the Philippines. In contrast, resistance to fipronil has developed only in WBPH in East Asia, Vietnam, and the Philippines. The LD50 values for imidacloprid in BPH in East Asia and Vietnam increased from 2006 to 2009, and have slightly decreased in 2010. In SBPH, an area-specific insecticide resistance has developed in Eastern China and Western Japan: the SBPH populations in Jiangsu Province, China showed resistance only against imidacloprid, whereas the populations in western Japan showed resistance only against fipronil. Migration of SBPH from Eastern China to Western Japan occurred in 2008; the following year local SBPH populations in Japan became resistant to both imidacloprid and fipronil. These populations were conceivably produced by the intercrossing between immigrant and domestic populations.

Mechanisms of pesticide-induced resurgence of the brown planthopper (BPH) *Nilaparvata lugens*

Xiang Jian Xu[1], Cai Jin Wu[2]

[1]*Yangzhou University, China,* [2]*Yangzhou University, China*

Stimulation of reproduction involved in direct stimulatory effect of pesticides on fecundity of BPH females and indirect stimulatory effect via physiological and biochemical alterations of rice plants due to pesticide application. These changes are beneficial to feeding, survival and fecundity of BPH. Studies of physiological and molecular mechanisms of pesticide-induced stimulation of fecundity showed that pesticides activated RNA transcript level in fat body and resulted in significant elevation of the gene expression level of vitellogenin (Nlvg) in fat body, which is regulated by the juvenile hormone esterase (Nljhe), which pesticides suppressed the expression of Nljhe and resulted in a significant elevation of JH level. Insecticides also stimulate the reproduction of adult males. The content of accessory gland proteins (AGPs) of treated males significantly increased. This stimulatory effect could be transferred to the reproduction of adult females via mating. Mating pair combinations of treated males and untreated males with treated females or untreated females showed that the number of eggs laid by the mating of treated males and treated females was significantly higher than that that of untreated males with treated females, showing that insecticide-induced the stimulatory effect of males could be transferred to the fecundity of females. Proteome analysis of mating pair combinations by 2-DE and LC-MS/MS showed that, of the 63 proteins identified, 38 were up-regulated and 25 were down-regulated. We have found some novel proteins related to fecundity including spermatogenesis-associated protein 5, PHD finger protein 7(NYD-SP6), agrinine kinase, actin-5C, vitellogenin, and ovarian serine protease nudel.

Ecological engineering for pest management in rice: Reconciling on-farm biodiversity and food security

Geoff Gurr[1], Zhong Xian Lu[2], Kong L. Heong[3], David J. Perovic[4], Jiaan Cheng[5], Chairat Channo[6], Gui Hua Chen[7], Ping Yang Zhu[8], Ho van Chien[9], Zeng Rong Zhu[10]

[1]Charles Sturt University, Australia, [2]Charles Sturt University, China, [3]International Rice Research Institute, Philippines, [4]Economic Development and Innovation, Australia, [5]Zhejiang University, China, [6]Thai Rice Department, Thailand, [7]Jinhua Plant Protection Startion, Australia, [8]Zhejiang Academy of Agricultural Sciences, China, [9]Ministry of Agriculture and Rural Development, Vietnam, [10]Zhejiang University, China

Rice planthoppers (Hemiptera: Delphacidae) have exhibited outbreaks in many Asian countries in recent years despite escalating levels of insecticide use. This particular system reflects the broader issue of global food security whereby the capacity of agriculture to meet the needs of a burgeoning human population is being questioned. One response is to rely on ever more advanced technologies (e.g. genetic and chemical) to make farms more intensive. In contrast, ecological engineering aims to design production systems that are more compatible with and exploit natural ecological processes. This paper will present results from a three-year, multi-country assessment of the efficacy of ecological engineering for enhancing biological control of rice pests. Cultural techniques, especially the planting of nectar-providing plants on the bunds around rice fields, have been implemented in China, Thailand and Vietnam and experimentally compared with a control treatment consisting of normal farmer practice with multiple insecticide applications. Growing nectar plants on bunds has proven popular with farmers because crops such as sesame can be used and these provide an additional income. Results show that natural enemy numbers and diversity are markedly enhanced under ecological engineering and that this leads to effective control of rice planthoppers. Numbers of insecticide sprays required in the ecological engineering treatment were far lower than in the control yet planthopper densities were well controlled and rice grain yields maintained. One indication of the broader ecological consequences of ecological engineering is that numbers of frogs were increased.

Flowering plants improve biological parameters of rice planthopper natural enemies

Zhongxian LV[1], Pingyang Zhu[2], KL Heong[3], GM Gurr[4]

[1]Zhejiang Academy of Agriculture Sciences, China, [2]Zhejiang Academy of Agriculture Sciences, China, [3]International Rice Research Institute, Philippines, [4]Charles Sturt University, Australia

Enhancement of biological control by ecological engineering requires an understanding of the benefit to key natural enemies of candidate plant species. Free-choice tests by using a Y-tube olfactometer showed that adult Anagrus nilaparvatae and A. optabilis , the dominant egg parasitoids of rice planthoppers in China, were significantly attracted to flowers of Impatiens balsamena, Emilia sonchifolia and Sesamum indicum (sesame) compared with a clean air control. Equivalent experiments with adult mirid bug Cyrtorhinus lividipennis, an important egg predator of rice planthoppers, showed attraction to flowers of Tagetes erecta and Emilia sonchifolia. Female adult longevity of A. nilaparvatae and A. optabilis were significantly enhanced in the presence of sesame flowers compared to water whilst T. erecta, sesame, E. sonchifolia and T. procumbens extended longevity of C. lividipennis female adults. The numbers of brown planthopper (BPH) eggs in caged rice plants parasitized by A. nilaparvatae and A. optabilis were almost doubled in the presence of sesame flowers. Predation of BPH eggs and fecundity of C. lividipennis were strongly improved by sesame, whilst more BPH nymphs were consumed in the presence of E. sonchifolia. No obvious difference was recorded in the attack rate of A. nilaparvatae on BPH eggs in rice plants between without and with sesame flowers, whilst handling time (Th) was reduced by sesame flowers. Th of C. lividipennis to BPH eggs was significantly reduced by sesame and T. erecta. Results indicated that growing sesame, a long-flowering plant, on the bunds of rice fields could effectively increase biological control of rice planthoppers.

Chemoreception systems and metabolic enzymes are two most crucial evolutionary traits for insects. The capacity to rapidly adapt to resistant rice varieties and to develop resistance to various insecticides has led to severe outbreaks of the three rice planthoppers over the last decade. Nilaparvata lugens is a typical monophagous plant-feeder with rice and its wild cultivars as its hosts whilst Sogatella furcifera and Laodelphax striatellus are oligophagous herbivores with broader host ranges. Using the genome and transcriptomes of them, we profiled their peri-chemoreceptor system and the Glutathione S Transferase family. Significant reduction of gene number and distinct clusters in the evolution were observed in N. lugens. Rice virus infection increased the gene level and altered the host selection activity. GSTs exhibited different induction pattern among three planthopper species, and rice virus infection also increased their level, indicating an interaction between the vector and the virus. RNA interference of GST genes significantly increased the sensitivity of nymphs to insecticides. Double-stranded RNA-transgenic rice lines were constructed with the odorant coreceptor OR83b gene and a GST gene from L. striatellus, seperately. When nymphs fed on the transgenic rice plants, expression level of targeted OR83b and GST were reduced and the sense to rice plant and sensitive to insecticides were affected. This study provides the first elucidation of the peri-chemoreceptor system and GST gene family in a monophagous arthropod. The use of RNA interference and dsRNA transgenic rice illustrates the likely mechanisms for the olfaction of these insects, and the tolerance of them.

The genome of *Nilaparvata lugens*

Chuan-Xi Zhang[1], Jia-An Cheng[2]
[1]*Zhejiang University, China,* [2]*Zhejiang University, China*

The brown planthopper, Nilaparvata lugens is the most destructive insect pest towards rice in Asia. In China, extensive outbreaks of rice planthoppers have been increasing in recent decades. These pests caused significant losses in rice yields through sucking, ovipositing and virus transmission (Cai et al., 2003; Wang et al., 2008). The BPH seriously threatens the world safety of food production. Regarding the influenced area and the people population, BPH is undoubtedly the most important agricultural insect pest around the world. Because of its long-distance migration, its quick adaptation to resistant rice varieties and development of high resistances to pesticides, N. lugens is difficult to adequately control. In this study, we present the draft 1,133 Mb genome of BPH, including its assembly, a set of 28,591 protein-coding genes. We also review findings of gene annotation efforts focused on genes related to migration and wing dimorphism, insect-plant interactions, symbiosis, detoxification, immune and virus transmission. The biological interpretation of the BPH genome provides a strong foundation for exploring the genetic basis of migration, of rice specialization and insect-rice interactions, of coevolved symbiotic associations and rice virus transmission, and of the pesticide resistance.

The brown planthopper (BPH), Nilaparvata lugens (Stal), is one of the most serious destructive insects of rice in Asia. The long-term application of chemical insecticides results in development of resistance against them. Also, development of biotypes being able to infest resistant rice varieties has been a serious problem to be solved. Accumulation of knowledge of N. lugens in genomic level will provide us clues to comprehensive understanding of development of insecticide resistance and new biotypes, which leads to sustainable pest management technologies. Although we have sequenced BPH ESTs derived from various tissues or developmental stages through Sanger techniques, genomic information of BPH has been unavailable yet. But recent advance in sequencing technologies have resulted in a dramatic reduction of sequencing costs and a corresponding increase in throughput. The situation above mentioned motivated us to start genome sequencing of BPH. In this report, we introduce the current status of genome sequencing and relevant ongoing projects. The BPH genome sequencing is conducted in combination of pyrosequencing (Roche/454 Life Sciences GS FLX) and Illumina Sequencing technology. So far, total length of 454 long reads and Illumina short reads reached about 7.2Gbp and 67.1Gbp, respectively. As for transciptome data, RNA-seq using various tissues, stages and strains are in progress. In addition, the genome sequencing of yeast-like symbionts (YLS) using NGS technology also is ongoing. In order to allow BPH researchers to utilize BPH genomic data efficiently, we are developing the integrated BPH genomic database.

Imidacloprid Resistance in the Brown Planthopper: Genes for nAChR Subunits and P450 Enzymes

Hiroaki Noda[1], Yuki Nakamura[2], Sawako Kawai[3], Yoko Koizumi[4], Yoshitaka Suetsugu[5], Toshinori Kozaki[6], Takaaki Daimon[7], Tetsuro Shinoda[8], Kimiko Yamamoto[9], Sachiyo Sanada[10]

[1]National Institute of Agrobiological Sciences, Japan, [2]National Institute of Agrobiological Sciences, Japan, [3]National Institute of Agrobiological Sciences, Japan, [4]National Institute of Agrobiological Sciences, Japan, [5]National Institute of Agrobiological Sciences, Japan, [6]National Institute of Agrobiological Sciences, Japan, [7]National Institute of Agrobiological Sciences, Japan, [8]National Institute of Agrobiological Sciences, Japan, [9]National Institute of Agrobiological Sciences, Japan, [10]National Agriculture and Food Research Organization, Japan

The brown planthopper (BPH) Nilaparvata lugens has recently exhibited remarkable resistance against imidacloprid, a neonicotinoid insecticide widely used for the chemical control of BPH. Insecticide resistance is usually caused by two main factors, namely, insensitivity to insecticides caused by gene mutation of insecticide target molecules, and high activity of the enzymes involved in insecticide detoxification. Gene mutation of the target molecule nAChR subunits has been reported in a laboratory-selected population of BPH. In contrast, field populations are reported to show high activity of P450 detoxification enzymes. We set out to elucidate the mechanism underlying imidacloprid resistance in BPH by using several resistant and susceptible strains. An [3H]imidacloprid binding assay did not show remarkable difference in binding level to membrane preparations of resistant and susceptible strains. In addition, comparison of the nucleotide sequences of nAChR subunits from multiple resistant and susceptible strains did not show common amino acid mutation sites between the two groups, suggesting that gene mutation is not currently involved in the imidacloprid resistance of field populations of BPH. In contrast, microarray analyses revealed that a P450 enzyme gene CYP6ER1 was commonly highly expressed in resistant strains. This gene has previously been reported to show high expression in other resistant strains, based on RNA-Seq data (Bass et al. 2011). The copy number of CYP6ER1 in the genome of resistant strains was estimated to be twice that of susceptible strains, suggesting that the high resistance level (~several dozen-fold) is mainly explained by the control mechanism of CYP6ER1 gene expression.

Sex ratio distortion by a male-killing Spiroplasma in the small brown planthopper, *Laodelphax striatellus*

Sachiyo Morimura[1], Masaya Matsumura[2], Hiroaki Noda[3]

[1]National Agriculture and Food Research Organization (NARO), Japan, [2]National Agriculture and Food Research Organization (NARO), Japan, [3]National Institute of Agrobiological Sciences, Japan

The small brown planthopper (SBPH), Laodelphax striatellus (Fallen) is a vector of rice and wheat plant viruses. We found the strongly female-biased sex ratio, i.e., 0.30 (proportion of males) in the Taiwanese (hereafter called the TW) and the slightly biased one, i.e., 0.43 in Japanese (the JP) strains. These strains harbored Spiroplasma, some strains of which are known to cause male-killing in some insect species. To determine whether Spiroplasma in the SBPH can manipulate their host reproduction, we carried out three examinations. First, Spiroplasma infection was examined by PCR in the TW and JP strains. The frequency of Spiroplasma infection was 0.86 in the TW strain, while it was 0.10 in the JP strain (N=50). Second, we established female-biased maternal lines (hereafter called FB lines) and non-biased maternal lines (NB lines) from these strains. Third, females of FB lines were treated with an antibiotic to eliminate the effect of symbionts. Tetracycline treatment cured the abnormal sex ratio of the progenies, strongly suggesting that symbionts manipulated their host reproduction. Since SBPH harbor Wolbachia (wStr), we established the maternal lines with single infection of Spiroplasma, which showed strongly female-biased sex ratio in their progenies. This is the first report of Spiroplasma-mediated-sex-ratio distortion in hemimetabolous insects.

Genes Regulating wing dimorphism of *Nilaparvata lugens*

Jian Xue
Zhejian University, China

The brown planthopper (BPH), Nilaparvata lugens (Stal), is an important insect rice pest in Asia. Wing dimorphism is a special physiological phenomenon to this species. Resulted from physiological differentiation, muscle content and its development showed significant difference between macropterous and brachypterous adults, especially for the indirect flight muscle (IFM) which only exists in macropterous adults. We compared the proteome profiles between IFM and the trochanteral depressor muscle. The result showed that proteins related to cytoskeleton, energy production and conversion, fatty acid and lipid metabolism, transcription and translation were different between them. After expression verification and location experiment, two proteins, flightin and TpnC4 were found to be specifically expressed in the IFM. RNA interference and flight ability tests showed that flightin played key roles in thick filament assembling and sarcomere stability, and both of the genes were important to the performance of the flight system. Together, macropterous BPH use these key genes to realize the functions of flight muscle and capability of flight. These data provide a potential explanation for the wing dimorphism of BPH, and offered a baseline for further studies on muscle differentiation in other wing dimorphism species.

Paired genome sequence reveals insights into intimate symbiosis in brown planthopper

Haiwei Fan[1], Jiaan Cheng[2], Chuanxi Zhang[3]

[1]zhejiang University, China, [2]Zhejiang University, China, [3]Zhejiang University, China

A number of plant-sucking insects harbor endosymbionts which are thought to play an important role in the development of hosts. As one of the most serious pests on rice, the brown planthopper (BPH) Nilaparvata lugens (Stal) harbors both fungal and bacterial symbionts. In this research, we performed paired genome sequencing of both BPH and its obligatory symbiont, yeast-like symbiont (YLS) which were preliminarily thought to have capacity to provide nutrition for the host. Concentrated on several vital nutritional biosynthesis pathways, annotation of metabolism genes reveals that the BPH lacks the capacity for de novo synthesis of essential amino acids and genes underlying the urea cycle. Complementarily, the YLS is able to support essential amino acid synthesis and nitrogen recycling. Besides, the intimate symbiosis relationship is also reflected on sterol and vitamin biosynthesis in BPH.

Fifty years of monitoring insect migration in the United Kingdom at Rothamsted

Jason Chapman[1], James Bell[2], Chris Shortall[3], Richard Harrington[4]

[1]Rothamsted Research, United Kingdom, [2]Rothamsted Research, United Kingdom, [3]Rothamsted Research, United Kingdom, [4]Rothamsted Research, United Kingdom

Rothamsted Research is the oldest agricultural research station in the world and has a long and illustrious history of studying insect migration, initiated by CB Williams in the 1920s. The ability to study country-wide spatio-temporal patterns of insect migration was greatly enhanced by the establishment of two national networks in the early 1960s. A network of 100 volunteer-run light-traps for sampling local macromoth populations was not designed specifically to study migration, but the spatial and temporal resolution of the data allows patterns of invasion to be monitored. The network of 12.2m high suction traps for sampling aphids and other small insects provides quantitative data on migration intensity and timing. These two networks have been complemented by continuous monitoring of high-altitude insect migration (between 150 and 1200m above the ground) by vertical-looking entomological radars since 1999. These three systems provide Rothamsted with an unparalleled capability for the study of insect migration. In this talk we discuss some recent results, with a focus on recently published work concerning pest aphids and moths, and Culicoides biting midges (the vectors of bluetongue and other animal viruses). Aphid phenology and abundance are affected by large-scale meteorological phenomena such as the North Atlantic Oscillation, and migratory patterns are better explained by aphid life-history traits than taxonomic relatedness. An important invasive moth pest (Autographa gamma) has been found further north in recent years and its population dynamics are dependent on a two-way migration. The flight season of Culicoides has been greatly extended over the past 40 years.

Management of Desert Locust

Keith Cressman
UN Food & Agriculture Organization (FAO), Italy

The Desert Locust is one of the world's oldest pests and the most dangerous and feared of all migratory locusts in Africa and Asia. The Desert Locust Information Service (DLIS) at the headquarters of the United Nations Food and Agriculture Organization (FAO) in Rome, Italy operates a global early warning system in order to reduce the frequency and duration of devastating plagues that can affect one quarter of the world's populations and their agriculture. The system makes use of the latest scientific and technical advances to monitor the weather, ecological conditions and locust infestations on a daily basis, forecast their developments and provide early warning on the scale, location and timing of locust breeding and migration. National locust survey and control teams in two dozen frontline countries, working in some of the most remote and inhospitable places on this planet, record their field observations in a handheld device, eLocust2, that transmits the data by satellite in real time to analysts and decision makers. DLIS uses a custom geographic information system (GIS), one of the first developed in the world for operational pest monitoring, to manage and analyze the data with remote sensing imagery, seasonal predictions, historical locust data and models that estimate development rates and migration routes. During the past three decades, a number of lessons have been gained that can be applied to other migratory pest monitoring and early warning programs.

Integrated Pest Management

Management of migratory *Helicoverpa* spp. moths in Australia.

Peter Charles Gregg[1], Alice P. Del Socorro[2], Kris Le Mottee[3]

[1]University of New England, Australia, [2]University of New England, Australia, [3]University of New England, Australia

The two major pest species of Helicoverpa in Australia are H. armigera and H. punctigera. Both are capable of long distance migration, but despite considerable research, uncertainty surrounds the frequency, extent and patterns of migration. H. armigera has been characterised as a facultative migrant, leaving cropping areas only when conditions are unfavourable, and often overwintering there. H. punctigera, by contrast, has been regarded as an obligate migrant, breeding in winter on native hosts in remote areas of inland Australia and migrating to cropping areas in the south and east every spring, when these hosts senesce with the onset of hot, dry weather. These differences have been invoked to explain differences in seasonal phenology and tendencies to develop resistance to insecticides and transgenic crops. However, recent trends have cast some doubt on these assumptions. Eastern Australia, and particularly inland regions, was affected by an unprecedented drought from 2001 to 2008, and this may have changed the capacity of inland regions to support H. punctigera populations or the migratory behaviour of the pests. Similarly, extensive deployment of transgenic (Bt) cotton in the eastern cropping areas may have affected the season population dynamics of both species. Understanding medium to long term changes in the migration systems of these pests is crucial for developing forecasting techniques for the crops affected (including many grains, oilseeds and cotton), and for devising Resistance Management Plans for Bt cotton.

Monitoring and Forecasting Australian Plague Locust Metapopulation

Haikou Wang[1], Edward Deveson[2], Alistair Drake[3]

[1]Fisheries and Forestry, Australia, [2]Fisheries and Forestry, Australia, [3]The University of New South Wales and University of Canberra, Australia

The Australian Plague Locust, Chortoicetes terminifera (Walker), is a widely distributed polyvoltine species with adapted mechanisms of diapause and quiescence, phase polyphenism, short-distance diurnal ranging and long-range nocturnal migration. It has 2-4 generations and frequently outbreaks which can cause severe damage to crops and pastures. Migration is crucial for its metapopulation persistence and plays an important role during plague. The Australian Plague Locust Commission (APLC) is responsible for monitoring Chortoicetes terminifera situation in eastern Australia, forecasting its population development and distribution, and carrying out control activities to minimise interstate migration. The APLC uses Normalised Difference Vegetation Index satellite images and rainfall distributions to monitor habitat conditions, and light-traps and fully-automated insect monitoring radars (IMR) to identify locust migrations in association with weather conditions and patterns. The APLC conducts routine ground survey within locust habitats, special follow-up in the region where migration is indicated by light-trap capture, IMR observed overflight, state- and public-report, and aerial surveillance when ground access is not practical or where a quick assessment of population level is required for searching suitable control targets. Thus the locust population development is simulated by a life-table model with localised locust and meteorological parameters and likely infestations are determined by a migration model which is based on wind trajectory analysis and locust orientation behaviours. The monitoring and forecasting of populations is essential for the APLC's decision-making and forms the basis of strategic control intervention. Migratory population exchange between the eastern and the western exists but is not significant or frequent.

Understanding the Migration of *Helicoverpa armigera* with Radar and Modelling the Area-wide Population Dynamics in Northern China

Hongqiang Feng[1], Kongming Wu[2]

[1]*Henan Academy of Agricultural Sciences, China,* [2]*Chinese Academy of Agricultural Sciences, China*

The cotton bollworm Helicoverpa armigera (Lepidoptera: Noctuidae) is one of the most serious biological disasters on multiple crops in northern China. Understanding the seasonal long-distance migration of H. armigera and accurately predicting the area wide population dynamics of this pest are essential to make effective control strategies. The seasonal high altitude wind born migrations of H. armigera have been observed with a scanning entomological radar and light traps in the past decade over both continent and the Bohai sea in northern China. The H. armigera moths migrated towards the north including over the Bohai sea at least as early as April, as soon as the moths had emerged from overwintering pupae and returned south on nights with northerly winds, or at altitudes where the wind was northerly during fall. Migrant H. armigera moths tended to fly at altitude where the wind direction, wind speed, and temperature were all optimum. A computer model has been developed based on the knowledge of biology and migration to simulate the population dynamics of this pest over a wide area in northern China. The model was validated with light-trap data and could potentially be used for forecasting the outbreaks of this pest and testing novel pest control strategies in northern China. This model also can be used to explore the resistance evolution in H. armigera to transgenic Bt crops in northern China.

Radar observation of the migration of rice leaf roller *Cnaphalocrocis medinalis* Guenee in southern China

Chunxian Jiang[1], Xiuli Yang[2], Huihui Qi[3], Yunhui Zhang[4], Dengfa Cheng[5]

[1]Institute of Plant Protection, Chinese Academy of Agricultural Sciences, China, [2]Chinese Academy of Agricultural Sciences, China, [3]Chinese Academy of Agricultural Sciences, China, [4]Chinese Academy of Agricultural Sciences, China, [5]Chinese Academy of Agricultural Sciences, China

The migration behaviors of Cnaphalocrocis medinalis Guenee in southern China were studied by using an 8.8mm wavelength scanning entomological radar, a searchlight trap and a conventional ground light-trap, field cages, systematic field survey and dissection of female ovarian in Xing'an Guangxi Zhuang Autonomous Region in China. The spatiotemporal distribution of landing areas of emigration population was analyzed using HYSPLIT, a software package that simulates migration trajectories. Results showed that the flight parameters of C.medinalis in southern China were different form that in eastern China. In southern China, C. medinalis started take-off behind 30min of sunset, reached the peak of take-off about 20:00, take-off can last 1-1.5h. C.medinalis generally flew below 1000m It can accumulate and form 2-3 layers dense layers when flew. The biggest density was at 400-500m. The insect layer was coincide closely with partial maximum wind speed and was not conincide with wind direction. However, the biggest density was not always at the height of biggest wind speed. Trajectory analysis showed that the population emigrating from Xing'an can arrive and survive at Liuzhou and Hechi in Guangxi Zhuang Autonomous Region, Huaihua and Xiangxi in Hunan province. Because of no suitable rice, the population arriving at Qiandongnan and Tongren in Guizhou province can't survive.

Overseas migration of the small brown planthopper, *Laodelphax striatellus*, in East Asia and its prediction

Akira Otuka[1], Yijun Zhou[2], Gwan-Seok Lee[3], Masaya Matsumura[4], Yeqin Zhu[5], Zewen Liu[6], Sachiyo Sanada-Morimura[7]

[1]NARO/Kyushu Okinawa Agricultural Research Center, Japan, [2]Jinagsu Academy of Agricultural Sciences, China, [3]National Academy of Agricultural Science, Republic of Korea, [4]NARO/Kyushu Okinawa Agricultural Research Center, Japan, [5]Nanjing Plant Protection Station, China, [6]Nanjing Agriculture University, China, [7]NARO/Kyushu Okinawa Agricultural Research Center, Japan

Rice cultivars grown in Jiangsu province in eastern China shifted in 1990s from those of the hybrid rice to japonica types of good taste that were susceptible to the small brown planthopper, Laodelphax striatellus, and the rice-wheat cropping system prevailed there. Since then, its density had started to increase and peaked in 2005. And rice stripe disease infected by the insects with high Rice stripe virus viruliferous rate spread to the whole of the province. Consequently, overseas migrations in early June started to appear in East Asia, subsequently causing severe outbreak of rice strip disease in Japan and Korea. To notice possible immigrations in advance, a new prediction method for the overseas migration of L. striatellus from eastern China to Japan and Korea has been developed. The method consists of two techniques: estimation of emigration period in the source region and migration simulation. The emigration period was estimated with the calculation of effective accumulated temperature for the insect using real-time daily surface temperatures in the source. During the emigration period, migration simulations were performed two times a day, or at every dawn and dusk. The prediction method was evaluated with a cross-validation technique against four-year events from 2008 to 2011. The result showed that the emigration periods included the mass migration events in 2008, 09 and 11 as well as an emigration peak in the source in 2010. The method was successfully predicted those events, and the overall hitting ratio was found to be 93 %.

The spring migration of the small brown planthopper, *Laodelphax striatellus*, in eastern China

Baoping ZHAI[1], Yangyang Hou[2], Yuan HE[3], Yonggang Diao[4], Li Wang[5], Haiyan Zhang[6], Haibo Yang[7], Yue Zhao[8], Chao Han[9], Yanbo Xu[10]

[1]Nanjing Agricultural University, China, [2]Nanjing Agricultural University, China, [3]Nanjing Agricultural University, China, [4]Nanjing Agricultural University, China, [5]Nanjing Agricultural University, China, [6]Nanjing Agricultural University, China, [7]Nanjing Agricultural University, China, [8]Nanjing Agricultural University, China, [9]Nanjing Agricultural University, China, [10]Nanjing Agricultural University, China

The spring migration of the small brown planthopper (SBPH), Laodeobhax striatellus (Fallen), were studied by field surveys in weeds, wheat and rice seedling fields, hourly collecting light-trap catches, ovarian dissection of macropterous females and trajactory analysis at four sites in eastern China in 2009 and 2010. The migration pathways of SBPH were simulated and analyzed by NOAA's HYSPLIT. The results were showed as follows: 1. The Spatial movements and dynamics of the spring population of SBPH in late May and the first half of June included long distance migration between different regions or overseas and local disperal among weeds, wheat fields and rice seedling fields. The adults dispersed from wheat fields to rice seedling plots just before wheat harvest, or when the taking-off SBPH were arrested by the weather conditions such as precipitation and strong winds. 2. The hourly collected light trap catches revealed that SBPH did migrate regularly after takeoff at dawn and dusk for a short or long journey, frequently, an all night fight. 3. The trajectory analysis illustrated that there were no definite spatial distribution for the source areas of the immigrant population of SBPH, so that both of the emigration and immigration could be seen in each research site and all of them were reciprocal source areas, which would be determined by wind fluctuation during the season.

Do rain initiate the take-off of the White-backed Planthopper, *Sogatella furcifera* during night?

Min Zhu[1], Lu Ji[2], Hailiang Zhang[3], Yang Hu[4], Ju Luo[5]

[1]China Jiliang University, China, [2]China Jiliang University, China, [3]China Jiliang University, China, [4]China National Rice Research Institute, China, [5]China National Rice Research Institute, China

The White-backed planthopper (WBPH), Sogatella furcifera (Horvath), is a major pest in rice production areas in China. It is also known as a typical migratory pest in Southeast Asia. Understanding of WBPH take-off behavior is critically important in studying the migratory processes of this pest, including source areas, migration pathways and landing places. In this study we focus on the relationship between WBPH take-off behavior and weather factors during night. Results suggested that: 1) WBPH take-off peaks occurred with rain during night; 2) WBPH undertake flights during dawn and dusk, and no take-off occurred during night without rain; 3) Total daily WBPH take-off number was not co-related with weather factors; 4) the sexual ratio was 1.2:1(female:male) during dawn take-off, and was 0.67:1 during dust take-off; 5) The night take-off rate was significantly positive correlated with relative humidity, and negatively correlated with temperature, and was not correlated with air pressure and vertical wind speed. These results suggested that further research on the mechanism to stimulate the ascent of WBPH was needed to better understand the take-off behavior during the emigration of WBPH in the field.

Subtropical High constructed meteorological conditions of the migratory field of *Nilaparvata lugens*

Gao Hu[1], Xianian Cheng[2], Baoping Zhai[3]

[1]Nanjing Agricultural University, China, [2]Nanjing Agricultural University, China, [3]Nanjing Agricultural University, China

Using 27 yr's (1977-2003) light-trap data of Nilaparvata lugens from 18 stations, the correlation coefficients between the light trap catches and indexes of the Subtropical High over the West Pacific were calculated. In June and July, area and intensity indexes of the Subtropical High have positive correlations with light-trap catches from stations which located in the lower-middle reaches of the Yangtze River. In the lower-middle reaches of the Yangtze River, the damage caused by N. lugens is usually more frequent and serious than that in other regions. The immigration peaks of N. lugens in this region began in June, and the biggest peaks occurred in 16-20 July. Using CMAP and NCEP/NCAR Reanalysis data, climate background in June and July were summarized. When the ridge line of the Subtropical High stood around 25°N from 18 June to 10 July, rain-belts, which may force N. lugens to land, located in the lower-middle reaches in the Yangtze River (27-34°N), and low-level jet, which provided a high-speed passage for insect migration, occurred in 23-30°N. When biggest peaks of N. lugens immigration in the lower-middle reaches of the Yangtze River occurred in mid-July, the rain-belts stayed in Huang-Huai Valley (34-38°N), low-level jet expanded to 34°N. When the Subtropical High was stronger than normal in June and July, the precipitation in the lower-middle reaches of the Yangtze River was more than normal, and in South China was less, and low-level jet was stronger. In that case, the meteorological condition was more suitable for N. lugens migration.

Shift of outbreak area of meadow moth in China and the response to climate warming

Xiao Chen[1], BaoPing Zhai[2]

[1]Nanjing Agricultural University, China, [2]Nanjing Agricultural University, China

Meadow moth is an important migratory pest in China and could cause serious damage to crops and pastures in outbreak years. Meadow moth have experienced three outbreak periods since the establishment of the People's Republic of China in 1949. Distribution patterns of meadow moth were analyzed based on historical monitoring records. The results showed that the serious damage area of meadow moth had shifted northwards evidently from north China (the permanent breeding area) to northeast China during the past three outbreak periods and climate warming was the main cause for this phenomena through changing their migration and overwintering patterns. In 1950s, the soil moisture in north China was much higher than now that means a favorable condition in vegetation, which would facilitate adults in north China to stay locally. But since 1970s, climate warming has resulted in serious draught and advanced the emerging time of adults in spring which has resulted in a noticeable deviation of the adult stage from the rainy season. Both factors could stimulate adults to migrate northwards frequently since 1970s. Due to the limit of temperature, meadow moth in eastern part of inn Mongolia could not finish two integrated generations in normal years, so seldom overwintering cocoons could be found in history. But since 1990s, with climate warming intensifying, there have been a notable increase in occurrence frequency of the second generation larva in northeast China and consequently, an increase in overwintering cocoons. That provides plenty of local source for the spring population in northeast China.

Geographic Variation of Dormancy in the small brown planthopper, *Laodelphax striatellus* (Homoptera: Delphacidae)

Yangyang Hou[1], Xiaoxi Zhang[2], Baoping Zhai[3]

[1]College of Plant Protection, China, [2]College of Plant Protection, China, [3]College of Plant Protection, China

Photoperiodic stimuli induces nymphal dormancy in the small brown planthopper, Laodelphax striatellus(Fallen). A study was wade of the effects of temperature and photoperiod on the developmental patterns of SBPH populations samples from Hanoi, Vietnam and Jilin, China. Under a series of standard laboratory conditions of temperature and photoperiod, the incidence of dormancy and rate of larval growth differed significantly between JiLin and Hanoi populations. The incidence of dormancy was positively correlated with the latitude of the population source. The characteristics of the temperature and photoperiodic responses differed between Jilin and Hanoi, indicating complex evolutionary trends. The populations differed not only in the effect of temperature and photoperiod on the incidence of dormancy, but also in the effect of temperature on larval growth speed. And there was also a geographic clime in critical photoperiod for dormancy.

A preliminary study on the behaviour mechanism of phototactic response of rice planthoppers

Haibo Yang[1], Baoping Zhai[2]

[1]College of Plant Protection, China, [2]College of Plant Protection, China

The behavior characters of rice planthoppers around the trap lights were discussed in detail through systematic investigation of population density and female ovarian maturity types. 1, The immigration period of WBPH and BPH in Jinhua rice field were before 10th and 20th August; the emigration period were after 11th August and 4th September, 2011. 3, Whether in immigration or emigration period, Both WBPH and BPH tend to threw themselves on the upstairs lamp, this result was caused by the phototaxis lag effect of rhythm responding to a trap light. 6, According to the funnelling effect, the movement distance of focal panthoppers was much longer than the effective range of light traps during one night; they kept one straight line when flying to lamp in horizontal direction; when the illumination was less than 556 lx, panthoppers shew positive phototaxis, when more than 556 lx, they shew negative phototaxis, the typical phototactic response was with a "?"shaped catching curve. 7, Generally, most planthoppers flew against the wind in the breeze when they threw themselves on a lamp; wend speed was not too strong, they can flew down the wind; wind speed was too strong, light-trap catches were very little. 9, The number of light-trap catches in without moonlight night was much than that of in moonlight night, the greater contrast between light and dark surroundings, the more amount of light-trap catches.

Modeling for insect pest management in fruit tree in Korea

Chuleui Jung[1], Jong-Geo Kim[2], Jeong Joon Ahn[3]

[1]Andong National University, Republic of Korea, [2]Andong National University, Republic of Korea, [3]Andong National University, Republic of Korea

Pest management is a complex process including information gathering, decision making, taking action against a pest and evaluation of the action. In pest management system, the qualitative or quantitative modeling of the pest population help decision making. In Korean apple and pear, 10 species of pests are in heavy management concerns including fruit borers, hemipteran insects and mites. Population model can be useful in projection of population size or population events such as peak or most damaging stage occurrence, which will determine the management timing. Here we summarized some of the research works on population model development for each species, implementation of the model frameworks to users(farmers), and the gap between the ideal management system and current field management practices. From this, we present the area of further development for ecologically sound pest management.

Matrix models for enhancing the role of biological control in IPM

Nick Mills
University of California, U.S.A.

Models can provide an effective framework to guide for the implementation solutions for the management of insect pests in agricultural crops. Here I discuss two different applications of stage structured matrix models for enhancing the role of biological control in IPM. The first application focuses on opportunities to improve the success of classical biological control in the management of invasive insect pests through guiding selection of the most effective natural enemy species for introduction their regions of origin. This is illustrated using a stage structured matrix model for Epiphyas postvittana, a leafroller pest that recently invaded California. Using this approach, the early larval stage was identified as the most vulnerable point in the life cycle and consequently that Dolichogenidea tasmanica should be selected as the most promising classical biological control agent. The second application focuses on conservation biological control and the evaluation of population-level consequences of natural enemy exposure to pesticides. The majority of bioassays conducted to determine the selectivity of pesticides with respect to natural enemies are based on individual-level endpoint measurements. It is important to estimate the population-level consequences of the measurements from these life table response experiments, however, and an important approach for this is illustrated using a stage structured matrix model for Trioxys pallidus, a parasitoid of the walnut aphid in California.

Modeling the spring emergence of *Grapholita molesta* in apple orchard

Jeong Joon Ahn[1], Lalit Prasad Sah[2], Chuleui Jung[3]

[1]Andong National University, Republic of Korea, [2]Andong National University, Republic of Korea, [3]Andong National University, Republic of Korea

The oriental fruit moth, Grapholita molesta (Busck) (Lepidoptera: Tortricidae) is one of important insect pests in Korean apple production. G. molesta overwinters as a full-grown larva within spherical and compactly woven larval-cocoons in the cleft of tree bark. In spring, the larvae develop to the pupa in the same place and adults emerge from late March or early April, then lay eggs on the tip of newly growing shoots of the host plant. Targeting management action on the egg and early larvae stages from the spring generation is critical to reduce the population of G. molesta during apple growing season. The model was developed to precisely predict the spring occurrence of G. molesta adults as a function of accumulated degree-days. Model validation was performed with the male moth catches in sex pheromone-baited traps in apple orchards in two major apple production regions (Uiseong and Geochang) of Korea in 2011. Five distribution models were applied to describe the cumulative proportions of G. molesta male caught relative to accumulated degree-days. The information-based approaches for analyzing observed data allow the data-based selection of a best model. The observed phenology of spring population of G. molesta was described by five models. The predicted dates for the cumulative 50% male moth catches were within five days variation. The performance of models was evaluated by statistical information criteria (AICC and BIC). The spring emergence model of G. molesta could be applied to determine optimal chemical treatment timing for controlling G. molesta in apple orchards.

Model simulation for IPM using DYMEX

Jung-Joon Park[1], Kijong Cho[2]
[1]*Korea University, Republic of Korea,* [2]*Korea University, Republic of Korea*

Population dynamics of greenhouse whitefly and American serpentine leafminer and pesticide application pattern of two-spotted spider mites (TSSM) were modeled and simulated using DYMEX model simulator. For population dynamics model simulation, leaf temperatures on reversed side of cherry tomato leaves were monitored according to three tomato plant positions using an infrared temperature gun. Air temperatures were monitored at same three positions using a temperature logger. The number of whitefly and leafminer were recorded by visual inspection and traps, respectively, to verify the performance of DYMEX simulation. A significant positive correlation between the observed and the simulated results was found when the leaf temperatures were incorporated into DYMEX simulation. This study demonstrated that the population dynamics of whitefly and leafminer were affected greatly by the leaf temperatures, rather than air temperatures in cherry tomato greenhouses. For modeling pesticide application pattern, we evaluated bioassay using TSSM in vitro. Four separated bioassay was evaluated at four different temperature conditions (20, 25, 30, and 35℃) with four commercial pesticides under commercial recommended dose. Mortality of TSSM were counted after 24 and 48 hours. A TSSM DYMEX model was developed and simulated under four temperature increasing scenarios (present condition, average 1, 2, and 3℃ increasing scenario) using DYMEX simulator. The DYMEX results showed that the pesticides application pattern were different among pesticides. In conclusion, the pesticide application should be changed for sound management of agricultural insect pest under temperature increasing scenario.

Development of the web-based information system for modeling insect population using site-specific weather data

Wee Soo Kang[1], Jongsun Park[2], Mun Il Ahn[3], Yong Soon Shin[4], Yong Kyu Han[5], Eun Woo Park[6]

[1]EPINET Corporation, Ltd., Republic of Korea, [2]EPINET Corporation, Ltd., Republic of Korea, [3]EPINET Corporation, Ltd., Republic of Korea, [4]EPINET Corporation, Ltd., Republic of Korea, [5]EPINET Corporation, Ltd., Republic of Korea, [6]Seoul National University, Republic of Korea

We developed the Agricultural Model Incubation System (AMIS) to support modeling research on plant diseases and insect pests. The system provides a web-based tool enabling users to run and verify their models using site-specific weather observation data or gridded weather data of 240m or 960m-grid size estimated for a certain region. The site-specific weather data is collected hourly from the public weather observation network. The gridded weather data is estimated from the site-specific weather data by using the geospatial interpolation method, Inverse Distance Weighting. Users can run models on hourly or daily basis and in various user-specific configurations by selecting time periods to run or by modifying model parameters. Output of the model run is provided to users in the form of maps or time series graphs, and downloadable through web browser. The system is capable of cohort-based simulation of insect population models using the site-specific weather data. At the moment, population models of 16 insect species, such as, Helicoverpa assulta, Grapholita molesta, Grapholita dimorpha, Myzus persicae, Sogatella furcifera, Laodelphax striatellus, Cnaphalocrocis dorsalis, Scirtothrips dorsalis, Unaspis yanonensis, Panonychus citri, Liriomyza trifolii, Trialeurodes vaporariorum, Bemisia tabaci biotype Q, Aphis gossypii, Frankliniella occidentalis, Spodoptera exigua, and forecasting models of 10 plant diseases are under verification and revision in the system. The verified models will be selected for application in web-based forecasting information systems. The system will be helpful for users to develop, validate, and analyze behavior of their models.

IPM Module for the Sustainable Management of Sugarcane Stem Borer, *Chilo infuscatellus* (Pyralidae, Lepidoptera)

Shahbaz Ahmad
University of the Punjab, Pakistan

Present study describes the evaluation of some environmentally sound tactics towards the management of sugarcane stem borer (Chilo infuscatellus). Different approaches were applied, Trichogramma cards, Detrashing, Light traps and Chemical control. The effects were found on the basis of incidence and intensity of Chilo infuscatellus. It was concluded from the results that the minimum infestation (8.71%) was recorded in T7 (Trichogramma cards + Detrashing + Light traps) which was statically at par with those of T3(Trichogramma cards + Light Traps), T1(Trichogramma cards + Detrashing) and T4(Detrashing + Chemical control) with increase in percent infestation 8.92%, 9.34% and 9.74% respectively. The treatment T8(Trichogramma cards + Chemical control + Light traps) showed 10.46% infestation was significant different from T6(Trichogramma cards + Detrashing + Chemical control), T9(Chemical control + Light trap +Detrashing) with infestation 11.66% and 11.86%. The treatment T2 (Trichogramma cards + Chemical control) with infestation 12.39% was statically at par with those of T5(Detrashing + light traps) with infestation (12.82%). The maximum infestation was observed in control treatment with 25.45%. The minimum infestation (11.66%) was recorded after 10 days interval while maximum infestation (12.53%) was observed after 20 days interval.

Modelling population dynamics of pest insects in paddy field

YongSu Kwon[1], Namil Chung[2], Mijung Bae[3], Fengqing Li[4], Young-Seuk Park[5]

[1]Kyung Hee University, Republic of Korea, [2]Kyung Hee University, Republic of Korea, [3]Kyung Hee University, Republic of Korea, [4]Kyung Hee University, Republic of Korea, [5]Kyung Hee University, Republic of Korea

In this study, pest insects in paddy fields were analysed to characterize the relationships between occurrence patterns of pest insects and their meteorological factors in space and time using a self-organizing map (SOM). The pest insect data with nine meteorological factors in the Korean national scale from 1992 to 2008 were obtained from the Agricultural Production and Environment Information Service System. Nine pest insect species showed clearly temporal and spatial difference for 17 years from 1992 to 2008. Occurrence patterns of pest insects in paddy fields could be classified into five groups by the SOM learning process based on their abundance patterns. Clusters I and II were characterized by the higher densities of Chilo suppressalis and Pseudaletia separate, whereas clusters III and IV were identified by the higher densities of Lissorhoptrus oryzophilus, Cnaphalocrocis medinalis, Sogatella furcifera and Scotinophara lurida. The cluster V displayed the lower densities of nine pest insects. These different patterns were significantly related with the differences in meteorological factors including temperature, precipitation and evaporation and by changes in agriculture processes such as cultivation methods and chemical fertilizer. Finally, our results suggest that the studies on the spatial and temporal variations in pest population dynamics provides insight into the factors determining population behavior as well as providing guidelines for pest insects' control.

Integrated Pest Management

Modelling complex interactions among organisms in paddy field

Il Hyo Jung
Pusan National University, Republic of Korea

The aim of this paper is to introduce a mathematical model for describing interactions among organisms ; paddy, weed, pest, natural enemy in a paddy field and to study a pest management problem in the paddy field. The model is basically a logistic, competitive, prey?predator model, predators being the pest and the natural enemy of the pest. For some pests, adult and nymph stage does harm for paddy, differently and so the model considers the pest population with two stages; immature and mature. This model will be applied to an integrated pest management problem to control pest populations in the paddy fiels, where release of sterile males and spraying of pesticide have been used as control measures for pest population. The sterile insect technique is one of the effective biological control for pests in the paddy culture system. Using optimal control theory, we show that the proper use of control measures might enhance the crop production of the model in an economically viable way. Using mathematical analysis, we have also found out an effective integrated pest management strategy.

Rice Farm? An integrated virtual system to predict the effects of climate change on the rice-ecosystem

Seung-Ho Kang
National Institute for Mathematical Sciences, Republic of Korea

RiceFarm is an integrated software system equipped with user friendly Graphic User Interface. The system is largely composed of three components. First one is the rice module. It is based on ORYZA 2000 which was developed by International Rice Research Institute in 2004. We modified ORYZA 2000 to accommodate to the virtual rice-ecosystem. Second one is the mathematical module which has the ability to predict the effects of climate change on the rice-ecosystem considering the interactions of spiders, pests and rice. In addition to the virtual ecosystem, RiceFarm included the socio-economic module. It enables us to produce the social and economic costs at advance caused by rice-ecosystem disturbance. We expect that RiceFarm would help to anticipate correctly the change of rice productivity according to the climate change and counteract to the change appropriately.

Catastrophe model and its application in insect ecology

Huiyan Zhao[1], Liang Zhang[2], Piyaratne Mkdk[3], Zheng Li[4], Qingxiang Meng[5]

[1]Northwest A & F University, China, [2]Northwest A & F University, China, [3]Northwest A & F University, Sri Lanka, [4]Northwest A & F University, China, [5]Northwest A & F University, China

Because there are widespread phenomenon that is led to catastrophic by continuous movement in nature, especially in the insect ecosystem, this phenomenon is more common. It is difficult to explain the phenomenon by traditional description of the continuous movement of the calculus method. Authors had not only established the catastrophe model of the folding, the cusp, but also the swallowtail, the butterfly, and the elliptical in the study of insect population dynamics, and using these models to explain, describe and predict the population dynamics of pests. It has give theoretical foundation for agricultural production and application examples. This article reviews the application and problems of catastrophe theory in the field of insect ecology since catastrophe theory set up, and future development directions.

Modeling strategies for pine wood nematode control

Chunlei Xia[1], Tae-Soo Chon[2], Chan Sik Jung[3], Young-Seok Park[4]

[1]Pusan National University, Republic of Korea, [2]Pusan National University, Republic of Korea, [3]Korea Forest Research Institute, Republic of Korea, [4]KyungHee University, Republic of Korea

Pine wilt disease is caused by the pine wood nematode Bursaphelenchus xylophilus, and the diseased spread by the pine sawyer beetle Monochamus altematus. Based on the individual beetle behavior, a mathematical model is proposed for evaluating control efficiency management of pine wilt disease in forest. The local rules regarding movement of vector populations (i.e., sawyer beetles) were applied on 2-D in the spatially structured models. Subsequently infested area was simulated in accordance with disease development. Population dynamics of pests was revealed in spatial and temporal domain. Intensity of control was further incorporated to the model. Asymptomatic carriers were considered in our model, the asymptomatic rate and nearest infestation distance were discussed through simulations. Finally, the control efficiency was predicted with different combinations of control areas and efforts. Optimized control strategy was further discussed.

Insect Biological Control

Endophytic bacteria: Potential of biological and symbiotic control

Paulo Teixeira Lacava[1], Welington Luiz Araujo[2], Thomas Albert Miller[3], Joao Lucio Azevedo[4]

[1]Federal University of Alfenas, Brazil, [2]University of Sao Paulo, Brazil, [3]University of California Riverside, U.S.A., [4]University of Sao Paulo, Brazil

Endophytes are microorganisms that do not visibly harm the host plant but can be isolated from surface-disinfected plant tissue. They colonize an ecological niche similar to that of phytopathogens, and this fact might favor them as candidates for biocontrol agents. Many endophytic bacteria have been isolated from sweet orange, but our research has focused on the genus Methylobacterium, which occupies the same ecological niche as Xylella fastidiosa, the causative agent of Citrus Variegated Chlorosis (CVC). The genus Methylobacterium is described as a main player in the interaction between the endophytic community and the pathogen X. fastidiosa. Xylem-feeding leafhoppers are unique organisms in terms of their nutritional ecology; they are able to feed from xylem fluid. A clear association has been observed between Cicadellinae leafhoppers xylem-feeding habit and ability to transmit X. fastidiosa. A new genetic transformation tool, called paratransgenesis, has been used to prevent the transmission of pathogens by insect vectors. Paratransgenesis means genetic alteration of symbiotic microbes that are carried by insects. The overall strategy of disease prevention is called symbiotic control. The key to symbiotic control is finding a candidate microbe having an existing association with the ecosystem. Based on the premise of symbiotic control, we genetically modified the citrus endophytic bacterium Methylobacterium and evaluated its capacity to colonize a model plant and its interaction with X. fastidiosa. This work reports the successful transformation of Methylobacterium generate two different strains with a different gene each, suggesting a possible strategy for the symbiotic control of CVC disease.

Insect Biological Control

Endophytic microorganisms : A review on insect control and recent advances on tropical countries

Joao Lucio De Azevedo
University of Sao Paulo, Brazil

Endophytic microorganisms inhabit plant tissues at least for a period of their life cycle, causing apparently no harm to the host. They constitute an alternative for the control of plant insect ?pests and diseases. They also help their hosts promoting plant growth and acting against stress conditions .Living inside plants, near pathogens, they are an ideal option to be improved by classical and molecular genetic methods. Many endophytic fungi and bacteria isolated from plant hosts are entomopathogenic . We have found these microorganisms as endophytes living in wild hosts from the Brazilian Amazon region and also from cultivated plant hosts. They were tested with success against insect-pests, cattle ticks and plant diseases from citrus, maize and eucalyptus among others. Also some endophytes were genetically modified, aiming to increase their protection against Citrus Variegated Chlorosis and other important plant diseases in Brazil.

Fungal endophytes and their potential for biocontrol in cotton

Gregory A. Sword[1], Maria Julissa Ek-Ramos[2], Diana Castillo Lopez[3], Wenqing Zhou[4], Cesar Valencia[5]
[1]Texas A&M University, U.S.A., [2]Texas A&M University, U.S.A., [3]Texas A&M University, U.S.A., [4]Texas A&M University, U.S.A., [5]Texas A&M University, U.S.A.

Asymptomatic fungal endophytes can provide protection to plants from a range of biotic and abiotic stressors. Included among these fungal endophytes are several species that are also known to be insect pathogens. Several fungal entomopathogens (e.g., Beauvaria bassiana, Lecanicillium lecanii and Paecilomyces spp.) can be both isolated from and inoculated to live systemically within a broad range of plants. As part of a survey of fungal endophyte diversity in cultivated cotton, we recovered a number of fungal endophytes that are known to act as antagonists against insects, plant pathogens, and nematode pests. In greenhouse trials, we successfully inoculated cotton seedlings using seed treatments of a field-collected endophytic strain of Paecilomyces sp. and a commercially available strain of Beauveria bassiana. In both cases, cotton aphid (Aphis gossypii) reproduction was significantly reduced on endophytically-colonized plants versus uninoculated controls in greenhouse performance assays. In a separate experiment, we tested for the endophytic colonization of plants cultivated under greenhouse conditions by B. bassiana when applied as a foliar inundative biocontrol agent to actively growing plants. We detected a high frequency (100-50%) of endophytic colonization of cotton leaves by B. bassiana for up to 21 days post-inoculation using both conventional culturing and a diagnostic PCR assay. Our results suggest that endophytic colonization of plants following the application of mycopesticides may be more common than previously realized.

Characterization and localization of novel proteins from *Antonospora locustae* (Protozoa: Microsporidae)

Zuyong Luo[1], He Leng[2], Guiqiang Wang[3], Long Zhang[4]

[1]China Agricultural University, China, [2]Heilongjiang University, China, [3]Heilongjiang University, China, [4]China Agricultural University, China

The Microsporidian Antonospora locustae is an obligate intracellular parasite that exists in over 100 orthopteran species that is used as a biological control agent. In our study, we performed 2-deminsional electrophoresis of the Lammeli extracts of A. locustae spore walls, and separated 9 protein spots on the SDS PAGE. Then we extracted proteins from the gel and performed to mass spectrometry. Finally, three proteins have been identified after blasted in A. locustae genome database. One of them is a protein with 131 amino acid, and molecular weight at 26.24 kDa, and has a signal peptide, named as AlocSWP1. The gene for this protein corresponds to the open reading frame 1184 in the A. locustae genome database. This protein has no transmembrane domain, but has a Ricin B-like lectin motif. Experiment on developmental expression of the Alocswp1 gene showed that the gene starts to express on the 13th day, when the sporoblasts are forming, after inoculation within the fat body of locust. Furthermore, the anti-AlcoSWP1 labeled the surfaces of layers of sporoblasts, and sporont as well as spore walls, this further demonstrated that the protein starts to express when the sporoblasts form. Most interestingly that it started to express where a new layer to add onto previous one. Besides expression in spore wall, it was observed to express in polar tube. Based on the facts we proposed that AlocSWP1 may be the protein as jointers between the layers of the spore wall and polar tube.

Insect Biological Control

Preference of different fruit scents to the natal fruit fly, *Ceratitis rosa* in a choice trial

Mkauena Margrett Lebusa
University of Kwazulu-Natal, South Africa

Ceratitis rosa (Natal Fruit Fly) is one of the most economically important pests of citrus fruits throughout the world. C. rosa like other fruit flies' status as a major pest is maintained on cultivated fruits because it is more abundant in both cultivated and wild fruits throughout the year. C. rosa has a wide range of hosts including the citruses as one of the most preferred cultivated hosts. Fruit fly management aims at deploying Bait Application Technique (BAT) which has been considered to control fruit flies over a large area. This can be achieved by using the "Attract and Kill" approach incorporating attractants in the form of food and pheromones. In this study fruit scents will be used as attractants in a bait station to attract flies to the killing agent. Flies have been introduced to the different fruit scents in a choice experiment to determine the most preferred scent/s and preliminary results have shown that orange scent (Limonene) and banana scent (Isomyl acetate) are the most attractive to the Natal fruit fly. Further trials will be carried out to further test the attractiveness of these scents in fruit fly baits.

Molecular pathogenesis of fungal entomopathogen *Metarhizium robertsii*

Qiang Gao[1], Zhibing Duan[2], Wei Huang[3], Chengshu Wang[4]

[1]Shanghai Institutes for Biological Sciences, China, [2]Shanghai Institutes for Biological Sciences, China, [3]Shanghai Institutes for Biological Sciences, China, [4]Shanghai Institutes for Biological Sciences, China

In contrast to entomopathogenic bacteria and viruses, entomopathogenic fungi infect insects via cuticular penetration. Work to date has shown that highly active classes of enzymes, in particular proteases, lipases and chitinases, play major roles in penetration and subsequent liquefaction of the internal organs of the insect hosts. Our studies on the entomopathogenMetarhiziumrobertsii provides insights into the novel mechanisms by which pathogen evade host immunity by masking cell wall componentsusing a cell surface collagen-like protein and producing toxic cyclopeptide secondary metabolites in insecta.Theadhesins MAD1 and MAD2 encoded by the fungus are used to differentially attach to insects or plants. We also found a mammalianperilipin-like protein MPL1 is involved in control lipid storage, appressorium turgor pressure and virulence. After reaching insect hemocoel, the fungus was found to up-regulate an osmosensorMOS1 and a bacterial-like phosphoketolase MPK1to modulate fungal adaptation and propagation in insect hemolymph. The results of these studies facilitate the understanding of fungal entomopathogenicity and thus the development of cost-effective mycoinsecticides.

Microbial endophytes as source for genes related to biological control

Welington Luiz Araujo[1], Juan Diego Rojas[2], Aline Aparecida Camargo Neves[3], Almir Jose Ferreira[4], Emy Tiyo Mano[5], Gabriel Padilla[6]

[1]University of Sao Paulo, Brazil, [2]University of Sao Paulo, Brazil, [3]University of Sao Paulo, Brazil, [4]University of Sao Paulo, Brazil, [5]University of Sao Paulo, Brazil, [6]University of Sao Paulo, Brazil

Researches for new molecules more effective against microbial diseases and pest control have been intensified in last few years due the development of the genomic and molecular biology approaches. This interest is also observed in obtaining pesticides with less environmental impact. In this context, endophytic microorganisms appear promising as a source of new species and therefore new metabolites. Studies showed that 51% bioactive compounds isolated from endophytic fungi have unknown chemical structure, thus, bioprospection of endophytes is considered an intelligent strategy to search for new compounds. Despite the increasing discovery of new compounds from endophytic fungi, there are a few studies involving knowledge of biosynthetic pathways responsible by their productions. Studies with endophytic bacteria Methylobacterium mesophilicum and Burkholderia cenocepacea and the fungus Epicoccum nigrum showed that these microorganisms are common inhabitant of plant tissues and extensive genetic variation can be found among isolates from a single location and host. Accordingly, to these characteristics these microorganisms are a source of new genes related to biological control of agronomic pests as well as production of new molecules that could be used for combinatory synthesis of many secondary metabolites. In order to identify these genes, we sequenced the genome of endophytic microorganisms and focused our studies in identification of genes related to polyketide synthases.

From random release to risk assessment: Developments during the last twenty years

Franz Bigler[1], Antoon J. Loomans[2], Joop C. Van Lenteren[3]
[1]Agroscope, Switzerland, [2]National Reference Centre, Netherlands, [3]Wageningen University, Netherlands

Classical Biological Control (CBC) of insects with non-native natural enemies has been applied for more than 120 years, and the release of more than 2000 species of natural enemies has resulted in the permanent reduction of at least 165 pest species worldwide. Augmentative Biological Control (ABC) with non-native and native natural enemies are periodically released and used for over 90 years. At present, about 230 species of natural enemies are commercially available worldwide to control about 100 pest species. While thorough environmental risk evaluations were made for natural enemies of weeds, routine pre-release risk assessments were made only exceptionally for invertebrate biological control agents (IBCAs) used in ABC and targeted against arthropod pests. From current literature and experience it becomes obvious that intentional introductions of IBCAs against arthropods are in general safe and it appears that less than 1% has caused lasting adverse population effects in non-targets. During the last twenty years, legal frameworks to regulate introductions of exotic species were established by several international organizations. Guidelines on information requirements are provided to serve the preparation of dossiers to support applications and assist risk assessors and decision makers in a balanced risk/benefit evaluation. Risk assessment methodologies and tools, based on relevant ecological criteria, have been developed and applied during the last decades. In our presentation we will review the developments of risk assessment of non-native IBCAs during the last two decades and show how the currently proposed methodologies improve the safe use of non-native IBCAs.

Selection of non-target species and host specificity testing of natural enemies: Cabbage seedpod weevil (*Ceutorhynchus obstrictus*) parasitoids as a case study

Marc Kenis[1], Tim Haye[2], Ulrich Kuhlmann[3]
[1]CABI, Switzerland, [2]CABI, Switzerland, [3]CABI, Switzerland

The assessment of natural enemies for biological control of pest arthropods has undergone a major change, particularly during the last 15 years. Concerns about the host specificity of several introduced natural enemies have resulted in the development of new frameworks for host range testing and calls for increased regulation of biological control, in order to confirm environmental safety of new agents. To evaluate potential impacts on non-target species we describe here a step-by-step procedure for selecting non-target species and for compiling a non-target species test list to assess the host specificity of new candidate entomophagous biological control agents. It is proposed that a set of categories, including ecological similarities, phylogenetic/taxonomic affinities, and safeguard considerations are applied to ecological host range information to develop an initial test list, ensuring that all aspects of potential impacts are considered. The initial list is then filtered to reduce the number of species to be tested by eliminating those with different spatial, temporal and morphological attributes and those species that are not readily obtained, thus unlikely to yield scientifically relevant data. The reduced test list is then used for a laboratory-based step-wise host range testing procedure that should allow over-and underestimation of the host range of a natural enemy to be avoided. On the basis of our own experience testing the host specificity of Trichomalus perfectus, a parasitoid of the cabbage seedpod weevil, Ceutorhynchus obstrictus, we discuss the practicality of the proposed procedure and the conclusions that can be drawn from the obtained data.

Measuring and predicting indirect non-target effects of new natural enemies

Russell Messing
University of Hawaii, U.S.A.

The potential environmental impacts of biological control agents include not only direct effects, but also more subtle indirect ecological interactions, such as competition and apparent competition. It is very difficult to analyze and predict the outcome of such relationships based on pre-release testing in a quarantine facility. However, regulators sometimes require such data, and biocontrol practitioners must be prepared to address these issues in order to minimize ecological risk, and to obtain release permits. A framework for considering both top-down and bottom-up non-target effects is presented. Descriptive studies (using small arenas, focal observations, and molecular and biochemical tools) and manipulative experiments (including large cage trials and surrogate experiments) can complement historical, theoretical, and phylogenetic considerations to approach the goal of providing a comprehensive overview and prediction of the biocontrol agent's role in an ecological community.

Host range testing for a new biocontrol agent for *Uraba lugens* (Lep.: Noctuidae) in New Zealand

Lisa Berndt[1], Toni May Withers[2], Barbara Barratt[3]
[1]Scion, New Zealand, [2]Scion, New Zealand, [3]AgResearch, New Zealand

Uraba lugens Walker (gum leaf skeletoniser) (Lepidoptera: Noctuidae) is an Australian pest of eucalyptus, now established in New Zealand. As a key part of developing classical biological control for this pest we conducted host range testing on its parasitoid Cotesia urabae Austin & Allen (Hymenoptera: Braconidae) to assess the risk it might pose to the New Zealand fauna. Host range tests were designed to examine physiological host range in the first instance, then, using choice tests and larger cage sizes, to increase ecological realism for the parasitoid. We found that although C. urabae preferred to attack U. lugens, it did show attack behaviour towards all of the eight species tested. However none of the non-target species supported successful development of adult parasitoids. Survival of parasitoid larvae inside attacked non-targets was limited to species from the most closely related subfamilies. We conclude that this parasitoid is unlikely to pose a significant risk to the few non-target species most closely related to U. lugens, and the risk to other species is extremely small. Based on this evidence, New Zealand regulators approved the application and C. urabae was released and successfully established in 2011.

Regulations for release of biological control agents in Brazil: The case of *Cotesia flavipes*

Vanda H P Bueno[1], Jose Roberto Postali Parra[2], Danilo S Pedrazzoli[3]
[1]Federal University of Lavras, Brazil, [2]University of Sao Paulo, Brazil, [3]Koppert Brazil, Brazil

Although biological control takes place on a large scale and several exotic natural enemies have been introduced into Brazil, legislation of import and release was for a long time not fine tuned for biological control agents. Biological control agents were exposed to the same legislation, including the same registration costs, as chemical pesticides. Due to the activities of the recently established Brazilian Association of Biological Control Industry (ABcBio) the situation has changed and currently 9 microbial agents and 3 natural enemies (Cotesia flavipes, Trichogramma galloi and Neoseiulus californicus) are registered. The most widely used natural enemy in Brazil is the exotic parasitoid Cotesia flavipes for control of Diatraea saccharalis on 3 million hectares of sugar cane. Only 5 companies, serving 2.5% of the area of sugarcane, have applied for and obtained a registration for use of C. flavipes, the other companies are actually producing and selling the parasitoid "illegaly". Registration is still a long process, taking about 36 months and involves the ministries of health, agriculture and environment. The recent arrival of foreign biological control companies, together with the current collaboration between the three ministries and ABcBio is expected to result in more efficient, cheaper and quicker registration of natural enemies in the near future. Examples of registration used elsewhere in the world are used to streamline and adapt the Brazilian legislation and will include quality control measures.

Environmental risk assessment of biological control agents in Canada: The cabbage seedpod weevil, *Ceutorhynchus obstrictus*, case study

Peter G. Mason[1], Tim Haye[2], Dave R. Gillespie[3], Jacob H. Miall[4], Gary A. P. Gibson[5], Ulrich Kuhlmann[6], Pat Bouchard[7]
[1]Canadian National Collection of Insects, Canada, [2]CABI, Switzerland, [3]Agriculture and Agri-Food Canada, Canada, [4]Canadian National Collection of Insects, Canada, [5]Canadian National Collection of Insects, Canada, [6]CABI Europe-Switzerland, Switzerland, [7]Canadian National Collection of Insects, Canada

In Canada, risk assessment of classical biological control agents is required as part of the regulatory process. To justify release, a major emphasis is placed on host range studies to determine potential breadth of non-target species attacked and levels of attack on suitable non-target species that may occur. Cabbage seedpod weevil, Ceutorhynchus obstrictus is an invasive alien pest of canola, Brassica napus, in Canada. Trichomalus perfectus, a potential classical biological control agent, has been assessed for safety. Results indicate that T. perfectus may not be suitable for introduction.

The Mediterranean basin as source of invertebrate biological control agents for northern Europe: Safe "exotics"?

Josep Anton Jacas[1], Alberto Urbaneja[2]
[1]*Universitat Jaume I, Spain,* [2]*Instituto Valenciano de Investigaciones Agrarias (IVIA), Spain*

In the past, Invertebrate Biological Control Agents (IBCA) released in European greenhouses in inoculative strategies were selected in northern European countries. Because of the mildness of climate, countries in the Mediterranean Basin are saw several of these IBCAs were able to establish. Several of these species used in inoculative releases have been considered risky for southern European countries. This problem, in combination with the recent limitations to the introduction of exotic natural enemies in Europe (and elsewhere) have prompted selection programs focused on IBCAs native to the Mediterranean Basin. Recent successes in biological control programs based on the use of these Mediterranean IBCAs (e.g. Eretmocerus mundus against Bemisia tabaci, Amblyseius swirskii against whiteflies and thrips, or Nesidiocoris tenuis against Tuta absoluta) and whiteflies) may have paved the way for future programs aimed at the selection of natural enemies safe for the whole western Palearctic eco-region. As they are native to Europe, these Mediterranean IBCAs could be safe for use in both northern European greenhouses (where permanent establishment would be improbable due to cold winters) andin the South (where they are already present). Because of the above mentioned reasons and the limited knowledge of the indigenous beneficial fauna occurring in the Mediterranean with many endemic species, studies focused on important groups of IBCAs in the Mediterranean Basin should be emphasized.

Insect Biological Control

Current regulations for import and release in Europe: How it is and how it should be

Johan Coert Vanlenteren[1], Antoon J.M. Loomans[2], Jeffey S Bale[3], Franz Bilger[4]

[1]Wageningen University, Netherlands, [2]Ministry of Economic Affairs, Agriculture and Innovation, Netherlands, [3]University of Birmingham, United Kingdom, [4]Agroscope Reckenholz-Tanikon Research Station, Switzerland

Over the last 120 years, there have been more than 5000 introductions of around 2000 non-native species of biological control agents for the control of arthropod pests in classical biological control programmes. Another 250 species are commercially available for augmentative biological control. All these releases have resulted in sustainable, environmentally friendly pest management, with very few reports of any negative effect. Still, world wide some 25 countries have regulatory systems for biological control agents and many more countries are developing regulation. The European Union is not (yet) regulating the use of natural enemies. As a result, there is a "patchwork of regulation" across Europe in which some countries have strict controls on the import of non-native species, while other, often neighbouring countries have no restrictions on the import and release of "exotic species". Within Europe, the IOBC/WPRS Commission "Harmonized Regulation of Biological Control Agents" developed together with the European Plant Protection Organization (EPPO) a standard providing guidelines for the import, release and required application procedures for non-indigenous biological control agents. This standard is based on an Environmental Risk Assessment of natural enemies. Several European countries are now using this standard to evaluate applications for import and release of natural enemies. In this talk we will summarize recent developments and explain how The Netherlands coped with the evaluation of 150 natural enemies already in use and with the and with 39 applications for 21 new species.

Insect Biological Control

History and present status of insect biological control in Japan

Masami Takagi
Kyushu University, Japan

here are three basic strategies in biological control; classical biological control, augmentative biological control and conservative biological control. The first attempt of the classical biological control in Japan was the biological control of the cottony cushion scale. Serious agricultural pests were frequently introduced into Japan after opening the country in 1858. Classical biological control was very effective against those adventive pests, which are well controlled by introduced natural enemies now. The first attempt of introduction of forging natural enemies was that of the vedalia beetle to the cottony cushion scale in 1911. After this success we introduced several natural enemies to control new adventives pests, such as the citrus spiny whitefly, the woolly apple aphid the red wax scale and the arrowhead scale. Biological control of the chestnut gall wasp and tea spiny whitefly will be reviewed in this symposium. The first practical attempt of the augmentative biological control in Japan was mass release of Phytoseiulus persimilis to control spider mites in 1969. Several kinds of natural enemies are used in augmentative biological control in Japan now. Many greenhouse farmers are using predatory mites to control not only spider mites but also small insect pests. The current status will be summarized in this symposium. Finally, a case study of conservative biological control in Japan, such as effects of companion plants for control of aphids in Isahay reclaimed land will be reviewed.

Research on the biological control of insect pests in Korea

Man-young Choi
Arysta LifeScience Corp., Japan

Research and development of technology about biological control in Korea was reviewed roughly. In 19th couple of classical biological control attempts had made against invaded pest species such as the wooly apple aphid, Eriosoma langigerum, in 1934. From 1995 forward most of the research about biological control was on the use of natural enemy for the control of insect pests occurring in protected cultivation. The research papers about biological control which have been published until 2012 were total 158, since 1965. Major insect and mite pests of greenhouse crops include aphids, thrips, whiteflies, fungus gnats, mealybugs, spider mites, leafminers and scales. In cucumber 62 pest species, in pepper (including paprika) 64 pest species, in tomato 54 pest species, and in strawberry 52 species pest species of insect and mite are recorded in Korea. However, among the many pests only a few species are considered as key pest. In cucumber, cotton aphid (Aphis gossypii), greenhouse whitefly, Palm thrips (Thrips palmi), and cotton caterpillar (Palpita indica) are often cause damage. In pepper, oriental tobacco budworm (Helicoverpa assulta), garden thrips (Frankliniella occidentalis), green peach aphid (Myzus persicae), and cotton aphid (Aphis gossypii) are major pests. In tomato, greenhouse whitefly (Trialeurodes vaporiorum), sweet potato whitefly (Bemisia tabaci), and america serpentine leaf miner (Liriomyza trifolii) are considered as key pests. And in strawberry, two-spotted spider mite (Tetranychus urticae), cotton aphid (Aphis gossypii), and Palm thrips (Thrips palmi) are often reach economic threshold level. There are 127 items of natural enemy products enlisted in the listing

Present status and future prospects of biological control in Thailand

Wiwat Suasaard
University Kamphaeng Saen Campus, Thailand

The diversity of biological control activities in Thailand ranges from basic biological information to the in time biological control of, mainly, the important agricultural pest insects. Such activities are made possible and substantial success accomplished through a national wide coordination. The exceptional current activities are in three streams: utilization of natural enemies for sustainable control of the outbreaks of cassava mealybugs complex, augmentative of biological control in black-headed caterpillars and coconut hispine beetles in coconut; and the management of pest insects for safety sugarcane production. Additional supporting research works include, utilization of natural enemies to control pest insects of economic crops; technology development of hymenopteran parasites, neuroptera lacewings, hemiptera and dermaptera predators and predatory mites, and, viability and package for transportation natural enemies and field release. With respect to the search for new agents, ongoing activities have been being facilitated the exploring, screening and efficacy test of the candidate endemic biocontrol agents. Consideration future prospects, besides the activities mentioned above, novel aspects of mass-production, packaging and utilization of those promising biocontrol agents, as well as, their shelf life for transportation prior to field release will be additionally investigated. One of the most important future prospects, without this the success of biological control program would not be achieved, is the acceptance of the farmers. Hence, demonstration plots, technology transfer and encouragement will be intensively conveyed to farmers to propagate natural enemies of their own.

Review of classical biological control in Japan: A case study of chestnut gall wasp

Kaori Yara[1], Seiichi Moriya[2]
[1]*National Agricultural Research Center, Japan,* [2]*National Agricultural Research Center, Japan*

Chestnut gall wasp Dryocosmus kuriphilus, accidentally introduced from China, was a serious pest of chestnut trees in Japan. This pest was first found in Japan in 1941 and spread throughout the country until 1960s. Because no effective pesticides and native natural enemies were available, the pest had once been controlled by using highly resistant chestnut varieties. However, a new biotype of D. kuriphilus appeared in Japan and exploited even those varieties around 1960. In contrast, we found that D. kuriphilus seemed not to be a serious pest in China. Thus, it was expected that there must be some effective natural enemies in China. After a preliminary survey of the natural enemies in China, a specialist parasitoid Torymus sinensis was selected as a candidate for control agent of D. kuriphilus; 260 mated females of T. sinensis were released at Tsukuba, Ibaraki Prefecture in spring of 1982. D. kuriphilus population at the release site was almost completely suppressed by the introduced parasitoids in 1990s. T. sinensis steadily spread in Japan, and the damage by D. kuriphilus drastically decreased in many Japanese chestnut orchards. Therefore, the introduction of T. sinensis is regarded as a typical example of classical biological control in Japan. However, there appeared some ecological and taxonomical problems to be solved (e.g. displacement of the native parasitoid T. beneficus by the introduced T. sinensis).

Biological control of the camellia spiny whitefly, *Aleurocanthus camelliae*, in Japanese tea fields

Atsushi Kasai[1], Koji Yamashita[2], Yutaka Yoshiyasu[3]
[1]Kyoto University, Japan, [2]Kyoto Prefecture, Japan, [3]Kyoto Prefectural University, Japan

Camellia spiny whitefly, Aleurocanthus camelliae Kanmiya & Kasai, infestations have been rapidly increasing in the tea-producing districts of Japan since its first occurrence in Uji, Kyoto Prefecture, in October 2004 (Kyoto Plant Protection Office, 2005). Aleurocanthus camelliae closely resembles the citrus spiny whitefly, Aleurocanthus spiniferus (Quaintance) and has been mistaken for A. spiniferus (Kanmiya et al., 2011). Honeydew excreted by A. camelliae nymphs promotes the growth of black sooty mold on tea leaves, and contamination with sooty mold and pupal cases of A. camelliae reduces tea leaf quality (Kasai et al., 2010). Because nymphs reside on the undersides of leaves, spraying a sufficient number of nymphs with pesticides is difficult. However, A. camelliae has a parasitoid wasp, Encarsia smithi (Silvestri), which controls the citrus spiny whitefly A. spiniferus. Field investigations have suggested that once the density of A. camelliae decreases to a low level, this wasp can keep A. camelliae at a low density. Because the density of E. smithi is reduced by the spraying of nonselective pesticides, such applications can cause a resurgence of A. camelliae. Therefore, pest control systems that use selective pesticides on tea fields are important for the efficient control of A. camelliae. In this presentation, we show a control system for A. camelliae that considers the performance of E. smithi and the phenology of A. camelliae in Japanese tea fields.

Insect Biological Control

Where is the real IPM in Asian biological control? Importance of registration and patent in IPM.

Tetsuo Wada
Arysta LifeScience Corp., Japan

Once Japanese biological control researchers were criticized by European researchers that Japanese IPM research is isolated from practical plant protection world and they just complain the fact ; i.e. actual plant protection was dominated by chemical pesticides. Not by IPM, neither by microbials nor natural enemies…. But this was also true in the EU and USA situation until recently. IPM firstly started in the USA mostly in outdoor orchard in California. The concept of IPM is fabulous and around 1985 the California spray calendar did not mention any chemical pesticide names but only mention biological control and physical agriculture plant protection procedure. Since late 1980s, the center of biological control moved north western Europe, namely to The Netherlands where Wageningen/AmsterdamUniv. and private sectors harmonized to develop new biological control solution. 20 years after, basis of the pest control in the green house is dominated by biological control in EU. And in Japan, it is realizing after 17 years from the first registration of Encarsia formosa till recent Swirskii mite. Registration and patent are the key to enhance and promote biological control. No company is interested to non-intellectual property based technology. No more copying in Asia in chemical and biological pesticides but more original discovery and inventions in the IPM technology is real necessity in Asian IPM.

Insect Biological Control

Present status and future prospects of natural enemy industry in Korea

Sung-Seung Yang
Arysta LifeScience Corp., Japan

Recently as consumer's concerns and needs for safe food increases, environmental-friendly farming which is known as not only the way to produce safe agricultural products in agriculture but also to protect the environment is getting more and more important. In environmental-friendly farming, it is the key technology to produce agricultural products without (or as less as possible) pesticide. Biological control based on natural enemy use is the most important pest control method in integrated pest management. The use of natural enemy for biological control is the fundamental technology to protect crop without chemical pesticide (eventually replace pesticide) or less pesticide use. Together with environmental-friendly farming, natural enemy industry has been developed and will be playing important role in the aspects. Now, Korean natural enemy industry has been developed much faster than the examples of other countries. But, except for the market leader Dongbu Ceres, most of the companies still remain at insufficient ability as a natural enemy producer, in the points of small scale of production, low level of technology, only few numbers of products, less capability of consulting for growers, etc. For further development of Korean natural enemy industry, it is required that such small natural enemy producers should make hard efforts on increasing their abilities on such aspects. It is expected that growers will produce safe agricultural products (that consumers are requiring) by the further development of natural enemy industry, and eventually environmental-friendly farming will be realized in much larger scale in Korea.

Commercial production of green lacewings, Mallada basalis (Walker) (Neuroptera: Chrysopidae) and its petty patent

Sopon Uraichuen[1], Rattigan Submok[2], Anuchit Chinajariyawong[3], Wiwat Suasa-ard[4]

[1]National Biological Control Research Center, Central Regional Center, Thailand, [2]National Biological Control Research Center, Central Regional Center, Thailand, [3]National Biological Control Research Center, Central Regional Center, Thailand, [4]National Biological Control Research Center, Central Regional Center, Thailand

Due to the disastrous outbreak of the cassava mealybug complex during 2009-2010 in Thailand, the commercialization of the green lacewing, Mallada basalis (Walker) and increasing its use in biological control was a challenge. One of the reactions to the challenge is to reduce the cost of mass-production. Therefore, research on process for a feasible commercial mass-production of the green lacewing, was intensively investigated in three main experiments. The initial one was to study food source for adult. Mixture of honey: yeast (1:1) was the most applicable one, giving 646.67 eggs/adult/month. The later experiment was done on food source for larvae rearing. Eggs of rice moth, Corcyra cephalonica (Stainton) efficiently provided greater number of eggs compared with feeding aphids, administering a net reproductive rate (Ro, /) 4.56, finite rate of growth (I, / /d) 1.135, cohort generation time (Tc, d) 36.368 days and capacity of increase (rc, / /d) 0.127. The final experiment was the interval feeding of larvae demonstrated that larvae fed with 2, 3 and 4 g of rice moth eggs on days 2, 6 and 8 of the initial of larval development, respectively, gave an average of 260 pupae from 300 eggs and subsequent 241.33 individuals survived to adults. By following the process described, 1.25 million eggs/month with an approximate production cost 16 US$ per one thousand eggs were successfully achieved. In addition petty patent for the mass-production of the lacewing has been registered since 2010 (Petty Patent No. 1003000360).

Fitness of the egg parasitoid *Trichogramma brassicae* is affected by size and shape of their host eggs

Tong-Xian Liu[1], Yong-Mei Zhang[2]
[1]Northwest A&F University, China, [2]Northwest A&F University, China

Size and shape of host eggs could affect the fitness of egg parasitoids. We determined the fitness of Trichogramma brassicae, one of the most important egg parasitoids of numerous lepidopteran pests, using Plutella xylostella egg, which is flattened, ellipsoid and small (0.0237 mm3), and Trichoplusia ni egg, which is spherical and large (0.0634 m3). The parasitoids were separately reared using the eggs of each of the two host species. The treatments included a no-choice of the eggs of each of the two host species and a choice of the eggs of both host species. The fitness parameters assessed including size of the parasitoids (hind tibia length), adult longevity, fecundity, number of adults emerged, number of conspecifics emerged per host egg, duration of development, and sex ratio in the no-choice experiments, and parasitism and sex ratio in the choice experiments. In the no-choice experiments, the parasitoids reared from T. ni eggs were larger, lived longer, oviposited more, more conspecifics emerged per host egg, developed faster, and parasitized more than from P. xylostella eggs. However, sex ratios of the offspring were not different when the parasitoid parasitized both species. In the choice experiments, the parasitoids killed more but parasitized less P. xylostella eggs than T. ni eggs. The sex ratio of the T. brassicae offspring reared from T. ni eggs was similar to that from P. xylostella eggs. These results indicate that the fitness of T. brassicae more favored spherical and larger host eggs than flattened and smaller host eggs.

Optimizing *Cotesia flavipes* (Cameron) release rates, and maximizing sugarcane yields for sugarcane borer complex in Thailand

Tewee Maneerat[1], Wiwat Suasaard[2], Oraphan Kernasa[3], Athitiya Kaewpadit[4]

[1]National Biological Control Research Center (NBCRC), Thailand, [2]Kasetsart University Kamphaeng Saen Campus, Thailand, [3]Kasetsart University Kamphaeng Saen Campus, Thailand, [4]National Biological Control Research Center (NBCRC), Thailand

Infestations of the lepidopteran sugarcane borer complex, Sesamia inferens (Walker), Chilo tumidicostalis Hampson, Chilo sacchariphagus (Bojer) and Chilo infuscatellus (Snellen), the most important pest insects of Thailand sugarcane plantations, occur annually. Two consecutive field experiments were performed with Cotesia flavipes (Cameron), a braconid biocontrol agent of the pest, in Central Thailand, with two objectives: to optimize rate and timing of field release of C. flavipes in order to suppress the pest infestations and to maximize the yield of sugarcane. Demonstration sites, in each experiment, were done in four field locations, two acres at each site, and in completely randomized block design. Results in the first experiment came out with the higher rate of release, the higher percent parasitisation obtained. With 375 and 500 adults release/acre yielded 22.48±4.03 and 25.12±3.77% parasitisation which were significantly higher ($P<0.05$) than those release with 125, 250 adults/acre and in control treatment (non-release), 14.81±4.11, 17.16±3.37 and 2.56±1.47, respectively. However, percent parasitisation in treatments, 375 and 500 adults/acre, were not significantly different ($P>0.05$). Later experiment, timing of release, with 375 adults/acre, appeared that monthly release of the parasites in 1-month old sugarcane sprouts gave 25.46±2.13% parasitisation and the sugarcane yield was 38.38 tons/acre which were significantly higher ($P<0.05$) than those in treatments, monthly release in 4-month old sugarcane; monthly release in 4-month old plus cut-off the insect-damaged shoots of sugarcane; and control (non-release). Percent parasitisation in the four later treatments were 21.42±4.31, 25.46±2.13, 21.48±2.00, and 6.20±0.91; and yields gained were 13.55±0.83, 14.68±0.37, 13.48±0.87 and 10.63±1.22 tons/hectare, respectively.

Insect Biological Control

Utilization of natural enemies for sustainable control of the outbreaks of cassava mealybugs complex in Thailand

Siriwan Tunkumthong[1], Sopon Uraichuen[2], Charida Sattayawong[3], Rattigan Submok[4], Wiwat Suasaard[5]

[1]National Biological Control Research Center (NBCRC), Thailand, [2]Kasetsart University Kamphaeng Saen Campus, Thailand, [3]National Biological Control Research Center (NBCRC), Thailand, [4]National Biological Control Research Center (NBCRC), Thailand, [5]Agricultural at Kamphaeng Saen, Kasetsart University Kamphaeng Saen Campus, Nakhon Pathom, Thailand

Annihilating outbreaks of the cassava mealybugs complex unexpectedly occurred in cassava plantations, covering 224,000 acres, in every part, except Southern Thailand in 2010. Hence, a biocontrol project was immediately initiated challenging the sustainable control of these pest insects. Precursory monitoring of the cassava mealybugs complex in fields noteworthy revealed five species of the pest insects; Phenacoccus manihoti Matile-Ferrero (first record in Thailand), Phenacoccus madeirensis Green Phenacoccus solenopsis Tinsley Pseudococcus jackbeardsleyi Gimpel & Miller and Ferrisia virgata (Cockerell). Later, approximately 8,200 acres of cassava plantations infested by the mealybugs were promoted for the use of natural enemies. With a total of 54.63 million natural enemies in seven highly potential species, namely, Plesiochrysa ramburi (Schneider), Mallada basalis (Walker), Allotropa sp., Wollastoniella rotunda Yasunaga & Miyamoto, Amblysius longispinosus (Evans), Orius maxidentex Ghauri and Geocoris ochropterus (Fieber) were mass-produced. Dissemination and augmentative releases were attained. Subsequently, one hundred intensive training and technology transfer courses were provided for 1,758 cassava farmers' participation, to exhibit the application of the biocontrol agents. Additionally, four naturally occurring of the mealybug plots, eight acres each, were conducted to demonstrate the bicontrol applications, with paired treatments, release and unrelease (control) of the natural enemies. There was a significant lower population density of the mealybugs in treated plots than those in untreated plots. Final assessment of the project was accomplished both in the satisfaction, in terms of questionnaire, of the participating farmers and the control of the pest insects. Approach and details will be inclusively given in oral presentation.

Conservation biological control of pest aphids by vegetation diversification: A successful example in potato fields of Japan

Kengo Nakahira
Kyushu University, Japan

Introduction: Vegetation diversification within farmlands by such methods as intercropping and companion plants naturally promotes pest suppression by enhancing the performance and abundance of natural enemies. Moreover, barrier plants reduce the immigration of pests into fields. Vegetation diversification within farmlands can a play plural role to suppress crop pests. In this study, the addition of barley strips were used as an example of vegetation diversification in outdoor potato fields of Japan. Methods: Three potato fields, two with barley strips and another of potato monoculture were prepared on reclaimed land in Isahaya City of Nagasaki Prefecture. Population dynamics of barley and potato aphids, and their natural enemies were investigated on barley strips and potato plants. Peak densities of potato aphids between conservation and monoculture fields and response of natural enemies between barley strips and potato plants were compared. Results: Barley strips supported different species of aphids compared to potato fields, but these different sets of aphids shared a common set of natural enemies. The amount of time between peak densities of aphid and their natural enemies was shorter in potato fields than in barley strips. The wingless and winged aphid populations in the field without barley strips was higher than in fields with barley strips, measured at peak aphid density. Conclusions: We have shown that barrier strips can potentially control aphids on potato plants by lowering colonization by aphids and by promoting larger and earlier immigration of aphid parasitoids and predators into potato fields.

Microbial control of cotton pests: Use of a naturally occurring entomopathogenic fungus (*Aspergillus* sp.) for managing *Creontiades dilutus* and beneficial insects on transgenic cotton crops in Australia

Robert Kofi Mensah[1], Leah Austin[2]
[1]*NSW Department of Primary Industries, Australia,* [2]*NSW Department of Primary Industries, Australia*

The development and adoption of transgenic (Bt) crops that express the Bacillus thuringiensis (Bt) toxin has reduced the use of synthetic insecticide on transgenic crops to target Helicoverpa spp., the major insect pest of cotton in Australia. However, it has also increased the threat posed by sucking pests, particularly Creontiades dilutus (green mirid), which are unaffected by the Bt toxins in transgenic cotton crops. The aim of the study was to determine the efficacy of an entomopathogenic fungus Aspergillus sp. (BC 639) in controlling the infestation of transgenic cotton crops by C. dilutus and promoting interactions of transgenic cotton with beneficial insects. The results showed that application of BC 639 fungus controlled the number of C. dilutus adults and nymphs similar to plots treated with the recommended concentration of the commercial insecticide fipronil. The fungus was found to have minimal effect on predatory insects compared with fipronil and was most effective against C. dilutus when applied at the rate of 500 ml/ha (equivalent to 50 g spores/ha). At this rate, the fungus was as effective as fipronil for controlling C. dilutus populations and ensured the survival of predatory beetles, lacewings and spiders compared with fipronil treatment. The ability of the BC 639 strain to control C. dilutus infestations of transgenic cotton crops while conserving beneficial insect populations suggests its potential for supplementing integrated pest management programs to reduce the use of synthetic insecticides for transgenic cropping systems.

Relative abundance of natural enemies of crop pests on *Bt*-transgenic and non-transgenic cottons in India

Mukesh Kumar Dhillon[1], Hari C. Sharma[2]

[1]Indian Agricultural Research Institute (IARI), New Delhi, India, [2]International Crops Research Institute for the Semi-Arid Tropics (ICRISAT), India

To ensure a sustainable deployment of insect-resistant transgenic plants, it is important that they are compatible with the natural enemies of crop pests. Reduced survival of the Campoletis chlorideae was recorded on Helicoverpa armigera larvae reared on Bt-transgenic cotton leaves, but these effects were due to early mortality of the host larvae, and possibly poor nutritional quality of H. armigera larvae. There was no significant influence of Bt-transgenic cottons on larval period, larval survival and adult emergence of the ladybird, Cheilomenes sexmaculatus fed on Aphis gossypii reared on Bt cottons. Monitoring of Bt-transgenic and non-transgenic cottons for natural parasitization of eggs and larvae of H. armigera at farmer's fields from South-central India revealed that there were no significant differences in Helicoverpa eggs (19.8% versus 20.9%) and larval (7.4% versus 9.6%) parasitism on Bt-transgenic and non-transgenic cottons. Trichogramma spp. parasitized the eggs, while C. chlorideae and Eriborus spp. parasitized the larvae of H. armigera. The field studies on the effects of Bt-cotton on the nontaget natural enemies indicated that there were no significant differences in the numbers of C. sexmaculatus grubs and adults, Chrysopa spp. larvae, and spiders on Bt-transgenic and their counterpart non-Bt cottons. The numbers of generalist predators such as ladybirds, chrysopids, and the spiders were significantly more in unprotected than in insecticide protected Bt-transgenic and non-transgenic cottons, suggesting greater negative effects of insecticides on the natural enemies in comparison to Bt-cotton.

Influence of transgenic *Bt* cotton on predacious arthropod assemblage and their impact on non-target pest suppression in Texas

Ram B. Shrestha[1], Megha N. Parajulee[2]

[1]Texas A&M University AgriLife Research and Extension Center, U.S.A., [2]Texas A&M University AgriLife Research and Extension Center, U.S.A.

Bt-transgenic cotton adoption in the United States cotton belt has exceeded 90% during the last 8-10 years. However, in the Texas High Plains, the largest contiguous cotton patch in the world, Bt-transgenic cotton adoption is nearing 70%. Overwhelming adoption of Bt cotton and widespread planting of Bt corn have reduced overall lepidopteran incidence across the U.S. cotton belt, and have the potential to exert indirect effects on non-target insect species. Reaching an understanding of these effects is the logical first step in developing ecologically-intensive IPM programs for Texas cotton. While Bt-transgenic cotton adoption has improved lepidopteran control in the Texas High Plains, non-target insect pests such as thrips, cotton fleahoppers, cotton aphids, and Lygus are becoming increasingly important. We investigated the impact of Bt-transgenic cotton on field populations of cotton aphids, thrips, and cotton fleahoppers, as well as the cotton insect predator complex, in Bt-transgenic (PM 2326BGRR) and non-transgenic (PM 2326RR) cotton cultivars. In the two-year experiments, Bt-transgenic cotton demonstrated significant negative effects on cotton aphid and cotton fleahopper populations, but no significant effects on thrips or foliage-dwelling predatory arthropod populations.

Honeybee foraging and pollination efficacy in Australian *Bt* cotton

Marwan Keshlaf[1], Robert Spooner-Hart[2], Robert Mensah[3]
[1]University of Tripoli, Libya, [2]University of Western Sydney, Australia, [3]NSW Department of Primary Industries, Australia

Although cotton is largely self-pollinating, previous researchers have reported that honeybees, Apis mellifera, can assist in cross-pollination and contribute to improved yield. Until the advent of GM (Bt) cotton, however, use of bees in cotton had been greatly limited by the excessive use of insecticides to control arthropod pests. Field trials conducted with honeybees in Bollgard II cotton crops in Australia over two consecutive years (using 8 and 16 hives/ha, respectively) showed that honeybees significantly increased cotton yield via increased boll set, mean weight of bolls, number of seeds per boll, and weight of lint per boll. Cotton flowers, and particularly cotton pollen, were not attractive to honeybees, and application of synthetic queen mandibular pheromone to flowers did not increase the level of bee visitation, nor boll set. Application of the insecticide fipronil at flowering against green mirid, Creontiades dilutus, in one trial severely reduced honeybee activity and its continued use will limit future opportunities for honeybees.

Insect Biological Control

Biological control of a cotton pest: *Bemisia tabaci* in Arizona transgenic cotton as a case study

Steven Naranjo[1], Peter Ellworth[2]

[1]*USDA-ARS, U.S.A.,* [2]*University of Arizona, U.S.A.*

The adoption of Bt cotton reached 25M hectares in 12 countries in 2011. While the technology has proven to be highly selective to targeted pests, several pest groups have become more problematic in certain regions. That has not been the case in the western USA and it is instructive to explore why this is so using Bemisia tabaci, a key pest of cotton in the southwestern USA, as a case study. We have shown that natural enemies, particularly native generalist arthropod predators, inflict high levels of mortality on this pest in multiple crops and non-crop hosts and that predation is a key factor in governing the population dynamics of B. tabaci in cotton. Over the past 15 years, we have developed and refined an IPM system for B. tabaci and other key pests of cotton that has as its center the conservation of natural enemies and maximization of their biological control service. The fundamental components of our integrated control program include a rapid and accurate monitoring program coupled with robust economic thresholds and highly selective insecticides that are used only as needed to supplement biological control. The mechanisms underlying the success of our approach have been elucidated through the construction and analysis of detailed, field-based life table studies. Since 1996, when our IPM program was introduced and Bt cotton production began, insecticide use has dropped nearly 90% and producers have enjoyed over US$388 million in savings from pest loss and insecticide costs.

Ecology of *Trichogramma* egg parasitoids in Australian transgenic cotton landscapes and their utilization for biological control

Andrew Davies[1], Christopher Carr[2], Brad Scholz[3], Myron Zalucki[4]
[1]CSIRO, Australia, [2]I&INSW, Australia, [3]DEEDIQLD, Australia, [4]University of Queensland, Australia

Helicoverpa (Hardwick) survivors are resurgent pests of Bt-transgenic cotton crops as they avoid transgenic tissue when feeding, especially when gene expression falters or wanes in the plant. Natural enemy impact is therefore advantageous when potentially disruptive conventional insecticides for Helicoverpa suppression are to be avoided. Trichogramma Westwood (Hymenoptera: Trichogrammatidae) egg parasitoids are the most utilised natural enemies in biological control programs worldwide. Generally, egg parasitoids fail to suppress Heliothine pests when mass released into cotton crops, primarily due to injudicious use of conventional insecticides, singly laid pest eggs avoiding detection, improved larval neonate survival at low densities, and asynchronous development benefiting pest over parasitoid. Despite this, relatively dense naturally occurring Trichogramma populations in the Ord River Irrigation Area (ORIA) of tropical northern Australia pervade local Bt-transgenic cotton crops and virtually negate Helicoverpa hatch. Although Trichogramma impact warrants inclusion in the local best management practice strategy for sustainable Bt-transgenic cotton production, reliance on conventional insecticides to suppress Helicoverpa survivors and other pests remains the status quo. When selective insecticides targeting secondary pests are applied judiciously, environmental conditions in ORIA cotton crops, especially early in the dry season, are conducive to Trichogramma proliferation and biological control of Helicoverpa is effective. There is scope, via habitat manipulation, to improve Trichogramma's suppression of Helicoverpa survivors in tropical Bt-transgenic cotton crops and there is evidence to support similar efforts in established Australian cotton growing regions.

Emerging pests and silver leaf whitefly; a challenge for Australian cotton systems.

Lewis Wilson[1], Simone Heimoana[2]
[1]CSIRO, Australia, [2]CSIRO, Australia

Silverleaf whitefly (Bemisia tabaci B-biotype, SLW) entered Australia in the mid 1990's and has progressively achieved pest status in all major cotton production regions. High adoption of Bt-cotton containing the Cry1Ac and Cry2Ab proteins has allowed dramatic reductions in pesticide use (from 8-12 down to <1) against Helicoverpa spp., the primary pest. Ironically, reduced spraying has allowed the green mirid (Creontiades dilutus) and green vegetable bug (Nezara viridula) to survive and they now require control (1-3 sprays). Control of these pests using broad-spectrum insecticides increases the risk of encouraging whitefly outbreaks. In addition, cotton pest management practitioners have noted that SLW were often more abundant in transgenic crops than conventional crops. Further, in small plot experiments okra leaf shaped genotypes appear to harbour fewer SLW. We compared SLW population development between Bt and non-Bt varieties, between okra leaf and normal leaf shaped varieties, and between sprayed (for mirids) and unsprayed systems. We found higher abundance of SLW on the non-transgenic cotton. Differences in SLW abundance between Bt and non-Bt in commercial crops are likely due to differences in spray regimes. Secondly, the okra leaf variety had significantly fewer SLW than the normal leaf cultivar, confirming valuable plant resistance. Finally sprayed cotton had higher abundance of SLW, indicating the detrimental effect on beneficial species. The results suggest a combination of okra leaf shape, transgenic cotton to reduce the need to spray, and use of selective mirid control will be options to help manage SLW.

Potential markets for stable industrialization of EPN business in Korea

Ho Yul Choo[1], Hyeong Hwan Kim[2], Dong Woon Lee[3], Young Moo Choo[4]
[1]Gyeongsang National University, Republic of Korea, [2]National Horticultural Research Institute, RDA, Republic of Korea, [3]Kyungpook National University, Republic of Korea, [4]University of California, U.S.A.

EPNs are important obligate biological control agents of insect pests and widely being used against a number of insect pests in several countries. Some of them are commercially produced in in vivo and in vitro. Although tasks to be worked out are still existed in commercial production and storage, marketing are also big issue for the development of EPN business. In Korea, commercial EPNs are being sold for the control of local and alien insect pests as the occasion demands. However, marketing has to be systematized for stable industrialization of EPNs. EPN markets should be expanded in these points. Many insect pests are occurred in greenhouse, propagation house of seedlings, golf courses, mushroom house, and so forth. Some crops or cultivating areas are restricted to apply chemical insecticides or hesitated to adopt chemicals by limited efficacies. For example, leaf beetles, sawflies, caterpillars, white grubs, fungus gnats, and many other insects are suitable targets to EPNs but sometimes cannot apply chemical insecticides by above reasons. The huge cultivating acreage of insect occurring crops or economic plants has searched for new alternative agents instead of chemicals. These may give big potential markets of EPN business in Korea. Thus, insects of important crops in each situation, efficacy of EPNs, and potentialities for EPN market will be discussed in this talk.

The status of entomopathogenic nematodes in biocontrol: Ushering in new era

Ramon Khedo Georgis
Brandt, U.S.A.

The Status of Entomopathogenic Nematodes in BioControl: Ushering in New Era Georgis, Ramon. Brandt, 2935 S. Koke Mill Rd, Springfield, IL 62711 USA Progress in nematode commercialization during 1990's and 2000's was phenomenal. Development in large-scale production technology, quality control, proper label directions and easy-of-use formulations led to the successful commercialization of the nematodes as biocontrol products in selected markets against specific target insects. Despite this progress, the reality is that insecticidal nematodes have not reached their anticipated market potential. This is attributed mainly to competitions from new pesticide and biological chemistries, short shelf life, and lack of proper support from the distributors. In addition to the need to optimize nematodes virulents and shelf life, the development of nematodes for effective insect control in the context of sustainable agriculture will be a major challenge in new era. A truly integrated approach is required, in which all agriculture practices, including other insect control options, should be considered to obtain maximum effect.

Wood borer control using entomopathogenic nematodes

Hiroshi Tanabe
SDS Biotech K.K., Japan

In recent years, the infestation of the wood borer is expanding in Japanese orchard and forest. Especially, Cherry treeborer (Synanthedon hecotor) infest to peach or cherry tree, Carpenter moth (Cossus insularis) infest to pear or apple and several other borers such as the long-horned beetles, ambrosia beetles damage and engrave heavily to the inside of wood trunk and it is not rare that the tree withers and dies. These wood borer infestations are increasing because of the change of cultivation system and management method, global warming and the increase of the orchard where the farmer give up cultivating. It is urgently needed to establish the effective control method. However it is difficult to success the enough efficacies by the chemical pesticide application because of the infestation area is inside of the wood trunk and the insufficient of distribution of pesticide to the gallery of wood borer which has complicated structure. Biosafe which is the entomopathogenic nematodes, Steinernema carpocapsae product in Japan is registered for many kinds of agricultural insect pests. Currently we have been proceeding the label expansion to the above serious wood borer species using the host finding ability of this nematodes species. In this presentation, the information about the application technologies and the field trials of several wood borer controls in our country are introduced.

Competitiveness assessment through current market and R&D trend of entomopathogenic nematode

Kyung Bon Koo[1], Ho Yul Choo[2], Hyung Chul Lee[3], Young Jin Lee[4], Young Sang Park[5]

[1]Eco Win, Republic of Korea, [2]Kyung-Sang University, Republic of Korea, [3]Eco Win, Republic of Korea, [4]Eco Win, Republic of Korea, [5]Eco Win, Republic of Korea

Recent worldwide efforts for environmental protection have brought an impact on all agricultural fields. This has led to an awareness of urgent transition to eco-friendly farming, and biopesticides such as entomopathogenic nematodes are receiving remarkable attention as a new concept in crop protection. Hereupon, competitiveness assessment through current market and R&D trends of entomopathogenic nematodes are needed. Global biopesticides market size were valued at USD 1.075billion in 2010, and Korean market was valued at USD 37 million, which is roughly 3% of the entire global market. Considering biopesticides based on soil microbial products, natural fertilizer and eco-friendly organic materials controlled under fertilizer control act and eco-friendly farming act, the market size is estimated at around USD 300 million. Natural enemy market size in Korea is estimated at USD 25 million in 2010 and it is expected to grow to USD38 million by 2012 and USD 81.5million by 2016. Upon evaluating competitiveness of biopesticides among the entomopathogenic nematodes market in our country, it can be concluded that Korea possesses superiority and progressive factors when compared with existing foreign technologies in terms of commercialization, mass production, long term storage, wide host range, host searching, lethal effect and cost effectiveness from mass cultivation of entomopathogenic nematodes.

Production technology and field application of entomopathogenic nematodes in China

Richou Han[1], Xuehong Qiu[2]

[1]*Guangdong Entomological Institute, China,* [2]*Guangdong Entomological Institute, China*

Entomopathogenic Steinernema and Heterorhabditis nematodes (EPNs) are the biological control agents which have the specific capacity to actively search and infect insect larvae in the soil. Recent advance in the solid and liquid production technology of EPNs has greatly improved the yield, quality, and shelf life of these beneficial worms in China, and stimulated the field application of these nematodes for the control of different insect pests. The factors influencing the production efficiency were explored, including medium development, optimization of the culture parameters (gas supply, inoculum size, bacterial status, temperature, etc), recovery of the infective juvenile (IJ) inocula, formation of IJs, extraction and harvest of IJs. A company called Century Horse Development Ltd, under the guidance of Guangdong Entomological Institute, is running. Healthy and reasonable products in solid culture system are provided for field trials in China and for internal and international markets. Production cost is still a limiting factor for further commercial development in the world nematode-based market. Ideal pest targets for these nematodes were evaluated. Apart from the important insect pests (such as flee beetle Phyllotreta striolata, and chive midge Bradysia odoriphaga) in vegetables, new invasive pests such as the oriental fruit fly Bactrocera dorsalis, asiatic palm weevil Rhabdoscelus lineaticollis and banana moth Opogona saccchari (Bojer) were also controlled by EPNs. In addition, transgenic Enterobacter cloacae with the insecticidal tcdA1B1 from symbiotic bacteria of EPNs was constructed and used for termite control. The transgenic bacteria also showed high toxic potential against Spodoptera exigua, S. litura and P. striolata.

Entomopathogenic nematology in North America

David Shapiro-Ilan
USDA-ARS, U.S.A.

Research and commercial application of entomopathogenic nematodes in North America has a long history. In the pursuit of commercial viability, there have been a number of success stories, but also quite a number of dead ends. In this presentation, we provide insight into new opportunities for entomopathogenic nematodes that are on the horizon. Some novel targets that are currently being researched include a variety of wood boring insects, weevil pests, as well as pests of pollinators. Novel application methods and formulations that are being developed will also facilitate expanded use of nematodes as microbial control agents. Advances in biocontrol will also be enhanced through fundamental studies on the microbial ecology, epizootiology, trait deterioration, population dynamics and genetics of entomopathogenic nematodes, as well as basic studies on host-pathogen relationships.

Bt Crops: Triumph of a creen technology based on *Bacillus thuringiensis*

Brian A Federici
University of California, U.S.A.

Over the past thirty years, numerous insect pathogens, including various viruses, bacteria, fungi, and protozoans have been evaluated as potential agents for controlling insect pests. Of these, only a few have been developed commercially for use in operational control programs. Baculoviruses, for example, were thought to have excellent commercial potential thirty years ago, but commercial use today is limited to a few special cases worldwide, on soybeans in Brazil, on cotton in Australia, on apples in the United States and Europe, and on potatoes in several countries in South America and northern Africa. Various fungi have also been investigated, but only recently have certain wild type and engineered strains of Metarhizium and Beauveria begun to show potential for use in controlling agricultural pests and mosquitoes. By far the most successful pathogens of insects developed commercially are strains of Bacillus thuringiensis (Bt) used for control of agricultural pests, primarily lepidopteran and coleopteran pests, and larvae of mosquitoes. Although successful, together all commercial bacterial insecticides constitute less than 1% of insecticide usage worldwide. In contrast to this, crops genetically engineered to produce Bt Cry proteins (i.e., Bt crops), mainly Bt cotton and Bt maize, first developed during the 1980's, now constitute a multi-billion dollar world market. These crops are grown on well over a hundred million acres in countries such as Australia, Argentina, the United States, Brazil, China, Korea, India, South Africa, and many others.

Insect Biological Control

Replication and transmission of the sexually transmitted insect virus HzNV-2

John P. Burand[1], Woojin Kim[2]

[1]*University of Massachusetts , U.S.A.,* [2]*Seoul National University, Republic of Korea*

The nudivirus HzNV-2 (aka Gonad Specific Virus, GSV) is the only, sexually transmitted, sterilizing virus yet identified infecting insects. Virus replication occurs principally in the reproductive tissues of infected insects causing the malformation of these tissues and sterility of the infected moth. In females, virus replication causes the cells in these tissues to proliferate with hyperplasia of the common and lateral oviducts. Eventually, progeny virus accumulates in a plug blocking the reproductive opening of the female which serves as a source of virus contaminating males as they attempt to mate. Virus replication has additional ramifications in infected females which produce more mating pheromones and as a result attract more mates than healthy females. Males attracted to infected females then become contaminated during mating attempts. Clearly HzNV-2 has evolved genetic properties which function to manipulate the physiology and behavior of infected insects facilitating virus transmission and enhancing viral fitness. In order to identify viral genes responsible for these properties, we have sequenced the genome of HzNV-2. In the analysis of the genome of the virus three ORFs were found that had significant sequence homology to cellular genes not previously found in any viral genome. These included a juvenile hormone esterase gene, a gene coding for a putative a zinc-dependent matrix metalloprotease, and a major facilitator super family protein gene. These unusual virus genes are believed to play an important role in the underlying molecular mechanisms used by the virus to manipulate the host to enhance its fitness and transmission.

The status and trends of *Bt* pesticides research in China

Jie Zhang[1], Changlong Shu[2], Fuping Song[3]

[1]Chinese Academy of Agricultural Sciences, China, [2]Chinese Academy of Agricultural Sciences, China, [3]Chinese Academy of Agricultural Sciences, China

The demand for biopesticides is rising steadily in all parts of the world. Public awareness about the environment is increasing, while pollution and health hazards due to synthetic chemicals are growing. Extensive and systematic research has enhanced the effectiveness of biopesticides, and as a result farmers and growers are using them in greater quantities.The economic value and ecological benefits make Bt attract peoples attentions and applied widely. In addition to the GMO , bio-pesticidesofBtisone of the most important andvaluable. New technique is promoting discovery of cry genes from native microbial resource. Hundreds cry genes were explored in recent five years. Status and trends of Btcry genes and pesticidesinChina will be introduced in the talk, as well asthe challenge and solutions in development of Bt bio-pesticides industry.

Possibility of *Lecanicillium* spp. for multiple pest control

Jeong Jun Kim[1], Mark Goettel[2], Dave Gillespie[3]

[1]National Academy of Agricultural Science, Republic of Korea, [2]Agriculture and Agri-Food Canada, Canada, [3]Agriculture and Agri-Food Canada, Canada

Entomopathogenic fungi have relatively high host specificity and can generally kill only one or a few species of insect pests. About 180 commercial mycopesticides have been registered world-wide using entomopathogenic fungi such as Beauveria bassiana, Metarhizium anisopliae and Lecanicillium spp. Their limited host range is one of the limiting factors for their commercial development. Recently it has been discovered that these fungi can also control plant pathogenic fungi such as Sphaerotheca fuliginea and Rhizoctonia solani. Previous studies demonstrated that an entomopathogenic fungal isolate could control either an insect or plant pathogenic fungus. Species of Lecanicillium are pathogenic to various host insects from caterpillar to aphids and whiteflies. At least 15 products based on Lecanicillium spp. have been commercialized. Three species of Lecancillium: L. longisporum, L. attenuatum and an unidentified isolate, have also recently been shown to kill 3 different species of aphids as well as suppress the growth and spore production of S. fuliginea in detached leaf disc bioassays. Under greenhouse conditions, a L. longisporum treatment reduced both cotton aphids and powdery mildew on cucumber leaves which were previously inoculated with aphids, powdery mildew or both. Through protoplast fusion of several isolates of L. longisporum, and L. muscarium, Japanese researchers have obtained Lecanicillium hybrids with multiple effects on soybean cyst nematodes, plant pathogens and insect pests, as well as colonization of soybean plant roots, making these strains promising for evelopment as broad spectrum biopesticides

Influence of synthetic media on mycelial growth and sporulation of the entomopathogenic *Aschersonia placenta* Berkeley & Broom

Dokgluaymai Homrahud[1], Sopon Uraichuen[2], Tewee Maneerat[3], Wiwat Suasaard[4], Anuchit Chinajariyawong[5]

[1]*National Biological Control Research Center (NBCRC), Thailand,* [2]*Kasetsart University Kamphaeng Saen Campus, Thailand,* [3]*National Biological Control Research Center (CRC), Thailand,* [4]*Kasetsart University Kamphaeng Saen Campus, Thailand,* [5]*National Biological Control Research Center (CRC), Thailand*

Aschersonia placenta Berkeley & Broom (Deuteromycotina: Coelomycetes), an entomopathogenic fungal species, is host specific to some aleyrodids and scale insects. Very little is known about the biology and ecology of this fungal species. Collection of the fungus from orange orchards in the East of Thailand was done to determine its colony growth and sporulation on seven synthetic media, PDA (Difco), PDAM (Difco), SDAY (Difco), SDAM (Difco), CMA (Difco), V8 and WA (Difco), at 25±2 °C and 75±5 % RH for a period of 21 days. The experiment was done in a completely randomized design allocated in 5 replications. The result showed that the colony radial growth (in cm) on SDAY (2.04±0.13) and SDAM (2.09±0.10) was not statistical different (P>0.05), but they were significantly different from PDA (1.49±0.06) and PDAM (1.49±0.09) (P<0.05). Importantly, on PDA and SDAY the concentrations of spore suspension were 2.59x109 and 2.69x109 spores/ml, respectively, which were non-significant different (P>0.05), but they were significantly different (P<0.05). from PDAM and SDAM with 1.02x109 and 2.17x109 spores/ml, respectively. Also CMA, V8 and WA produced weak mycelia and sporulation; therefore, PDA and SDAY were the appropriate media for laboratory cultures of A. placenta.

Current status of microbial control using insect viruses in Japan

Madoka Nakai
Tokyo University of Agriculture and Technology, Japan

The economic importance of microbial control agents is currently increasing in Japan. The most widely applied microbial control agent is the bacterium Bacillus thuringiensis, followed by entomopathogenic fungi and viruses. Among various insect viruses, baculoviruses are the only group used as microbial control agents at present. In Japan, two products based on baculoviruses are currently registered as biocontrol agents: one is a mixture of two granuloviruses (GVs) to control leaf-rollers (Adoxophyes honmai and Homona magnanima; Lepidoptera, Tortricidae) in tea fields, and the other is a nucleopolyhedrovirus (NPV) to control armyworm (Spodoptera litura, Lepidoptera, Noctuidae) on a variety of crops. These virus agents have been essential to control specific pests which have acquired resistance against chemical pesticides. The A. honmai and H. magnanima GVs are well adapted to control leaf-rollers in the tea system, and are also suitable for virus production using living insects. A notable feature of this host-pathogen system is that a single virus application was able to suppress the leaf-rollers throughout a whole year, during which four generations of the pest species normally occur in Japan. This was because the virus kills the host slowly, allowing active progeny virus to transmit itself to young insects in the next host generation. The NPV was originally registered to control S. litura on strawberry, lettuce, edamame (immature soybean) and soybean. However, its usage has broadened recently to include certain minor crops for which fewer registered chemical pesticides are available, such as shiso (Japanese basil), asparagus and edible chrysanthemum.

The negative control of crystal protein gene expression in *Bacillus thuringiensis* YBT-1518

Xiaoxia Luo[1], Donghai Peng[2], Suxia Guo[3], Lifang Ruan[4], Ming Sun[5]

[1]Huazhong Agricultural University, China, [2]Huazhong Agricultural University, China, [3]Huazhong Agricultural University, China, [4]Huazhong Agricultural University, China, [5]Huazhong Agricultural University, China

Bacillus thuringiensis forms proteinaceous crystals during sporulation that can account for 20-30% of the dry weight of the sporulated culture. There are many reports focused on the positive expression mechanism of the crystal proteins. But there is few on negative control. Here we present the negative control of crystal protein gene expression in B. thuringiensis YBT-1518 which produces rice-shaped protein crystals with 2 components of molecular mass 45 kDa (cry55Aa) and 54 kDa (cry6Aa) and are toxic to root-knot nematode. Previously, we found the expression of cry6Aa gene was negatively controlled by a gene named R2. While in other case, we isolated the third crystal gene cry5Ba (Guo et al., Appl Environ Microbiol. 74: 6997?7001, 2008). But in strain YBT-1518 we cannot observe the expression of Cry5Ba under the detection with an optical microscope and SDS-PAGE. After eliminating the plasmid which harbors cry55Aa and cry6Aa, there is not effect on the expression of Cry5Ba. RT-PCR detection showed a transit transcription at the onset of the stationary phase. More than 10kb flank sequences (each side) of cry5Ba can not be found to affect the expression of Cry5Ba. After finishing the genome sequence and bioinformatics analysis, a gene locus BMBsr1 which reversely complements the ribosome binding site of cry5Ba was predicted as a sRNA coding sequence. By gene knock-out and heterologous expression, gene BMBsr1was found to inhibit the expression of Cry5Ba in strain YBT-1518. When applying gfp and lacZ as report marker, BMBsr1 was found gene silencing effect either.

AcMNPV infection suppresses the expression of host immune and juvenile hormone-regulated genes in *Spodoptera exigua* larvae

Jae Young Choi[1], Yeon Ho Je[2]
[1]*Seoul National University, Republic of Korea,* [2]*Seoul National University, Republic of Korea*

The impact of Autographa californica multicapsid nucleopolyhedrovirus (AcMNPV) infection on host gene expression in Spodoptera exigua 4th instar larvae was investigated through the use of 454 sequencing-based RNA-seq of cDNA libraries developed from insects challenged with active AcMNPV or heat-inactivated AcMNPV. By comparing the two cDNA libraries, we show that 201 host genes are significantly up-regulated and 234 genes are significantly down-regulated by active AcMNPV infection. Down-regulated host genes included genes encoding antimicrobial peptides, namely three gloverin isoforms and an attacin, indicating that the viral infection actively repressed the expression of a portion of the host immune gene repertoire. Another interesting group of down-regulated host genes included genes encoding two juvenile hormone binding proteins and a hexamerin, all of which are involved in juvenile hormone regulation. The expression of these genes was enhanced by the topical application of Juvenile Hormone III (JHIII) in the insects challenged with heat-inactivated AcMNPV. However, infection with the active virus strongly suppresses the expression of these three genes, regardless of the absence or presence of JHIII. Using RNA-seq, we have identified groups of immune-regulated and juvenile hormone-regulated genes that are suppressed by infection with active AcMNPV. This information and further studies on the regulation of host gene expression by AcMNPV will provide the tools needed to enhance the utility of the virus as an effective protein expression system and as an insecticide.

Events of mycosis hotbeds in Colorado beetle populations in the South Urals from 2008 to 2011

Elena Surina[1], Konstantin Kitaev[2], Galina Benkovskaya[3]

[1]Institute of biochemistry and genetics USC RAS, Russia, [2]Institute of biochemistry and genetics USC RAS, Russia, [3]Institute of biochemistry and genetics USC RAS, Russia

Biocontrol of pest insects is one of the main branches of modern science research. Entomopathogenic fungi take up significant place in this issue. Colorado potato beetle was found in Bashkortostan in 1976. Mass infection by entomopathogenic fungi was found in 2008 for the first time. Analysis of level of infection was started in this year. 76 excerpts from 33 districts were assayed from 2008 to 2011. Beetles with manifestation of mycosis were taken post mortem during toxicological assay. Maximum value of infected individuals (80%) was observed in 2009 year in west region, whereas maximum values in 2010 and 2011 years were 30 and 38 %, recently. Hotbeds were noted in central and north regions. Isolates were obtained from Colorado beetle cadavers collected in all hotbeds. Isolates refer to genus Beauveria. A total of isolates were characterized by RAPD-PCR. Percentage polymorphic loci (P), Shannon's information index (Is), Nei's genetic diversity (h), total genetic diversity (Ht), genetic diversity within group (Hs) and the relative magnitude of genetic differentiation among groups (Gst), genetic identity (I) and genetic distance (D) were calculated for all pare-wise combinations of groups. Dendrograms were constructed by cluster analysis based on the unweighted pair group method with arithmetical means (UPGMA). Our investigation shows degree of phylogenetic relationship between different isolates of enthomopathogenic fungi from population of Colorado potato beetle in the South Ural. Investigations funded by Russian Foundation for Basic Research 11-04-01886_a and 11-04-97022-r_povolzye_a.

Recent studies on the thermotolerance of entomopathogenic fungi

Jae Su Kim[1], Yeon Ho Je[2], Bruce L Parker[3]
[1]Chonbuk National University, Republic of Korea, [2]Seoul National University, Republic of Korea, [3]University of Vermont, U.S.A.

For successful commercialization of entomopathogenic fungi a problem of low thermotolerance must be overcome. To increase thermotolerance the effects of nutritional manipulation of culture media and oil-coating of conidia of Beauveria bassiana and Metarhizium anisopliae isolates were investigated, followed by pairing of similar isolates. Millet grain and whey permeate-based cultures produced more thermotolerant conidia than ¼SDAY cultures. Conidia produced on millet or whey permeate were more hydrophobic and exhibited greater thermotolerance than those produced on ¼SDAY. The mycotized millet grains were further coated with plant oils. Conidia with a corn oil coating were superior to sunflower- and cotton seed oil coatings in thermotolerance. Pairing of two B. bassiana isolates was done to generate new colonies with enhanced thermotolerance by possible transcriptional alteration. One colony with completely different morphology was isolated from the paired culture and it had the highest thermotolerance without significant loss of virulence. Recently, thermo-susceptible B. bassiana mutants were generated by a fungal transformation platform to discover thermotolerance-related genes, which are now under determination. These results suggest that the thermotolerance of entomopathogenic fungi can be increased by the nutritional manipulation, oil-based coating and pairing. Genetic information on fungal thermotolerance is going to be clear in near the future.

Identification of three new Cry proteins synthesized by *Bacillus thuringiensis* subsp. *jegathesan*

Yunjun Sun[1], Liqiu Xia[2], Qiang Zhao[3], Brian A. Federici[4], Hyun Woo Park[5]

[1]Hunan Normal University, China, [2]Hunan Normal University, China, [3]Hunan Normal University, China, [4]University of California, U.S.A., [5]California Baptist University, U.S.A.

Bacillus thuringiensis subsp. jegathesan is known to produce at least five 'mosquitocidal' proteins ? Cry11B, Cry19A, Cry24A, Cry25A and Cyt2B. Among these, however, Cry11B is the only protein that shows high larvicidal activity, indicating that there could be other unknown mosquitocidal proteins produced by this bacterium. Through mass spectrometric analysis of proteins separated by polyacrylamide gel electrophoresis, three additional Cry proteins were discovered in this strain. PCR amplification and sequencing of their coding genes revealed that each was encoded by a novel gene, which were designated, respectively, as cry30Ca2, cry60Aa1 and cry60Ba1. Interestingly, cry60Aa1 and cry60Ba1 occur as an operon, and were also found in B. thuringiensis subsp. israelensis (ATCC35646). When these Cry proteins were produced using the cyt1A-p/STAB system in acrystalliferous B. thuringiensis 4Q7, Cry60Aa1 and Cry60Ba1 assembled into one large crystal per cell, whereas Cry30Ca2 did not form a crystal. The median lethal concentrations (LC50s) of Cry60Aa1, Cry60Ba1, and Cry60Aa1+Cry60Ba1 were 5.5, 7.9 and 2.9 μg/ml, respectively, when they were tested against early 4th instars of Culex quinquefasciatus. In addition, SDS-PAGE analysis indicated that co-synthesis of Cry60Aa1 and Cry60Ba1 may interfere with each other's synthesis by an unknown mechanism.

Nasonia genomics and the genetic improvement of parasitoids for biological pest control

John H. Werren
University of Rochester, U.S.A.

Parasitoids are used widely in biological control of insect pests. One method is augmentative release, which involves mass-rearing of parasitoids and release into human modified habitats (e.g. crop fields, greenhouses, barns) to suppress pest numbers. However, these methods mostly use "wild" parasitoids. An approach for the future will be to "domesticate" parasitoids for improved biocontrol agricultural systems. To achieve this goal, a better understanding of the genetics and genomics of parasitoids is needed. Genomes of three related parasitoids in the genus Nasonia have recently been sequenced. Promising traits for parasitoid domestication are discussed, along with findings from genomic and genetic studies of Nasonia relevant to the issue of parasitoid improvement in biological control.

Genetics of hymenopteran sex determination

Eveline C. Verhulst[1], Louis van de Zande[2], Leo W. Beukeboom[3]
[1]University of Groningen, Netherlands, [2]University of Groningen, Netherlands, [3]University of Groningen, Netherlands

Sex determining mechanisms are bewildering diverse and turn over rapidly in evolution. Sex determination in insects occurs through a cascade of genetic switches with conserved genes at the bottom but strong diversification in the primary signal genes. I will discuss the genetic regulation and phylogenetic pattern of sex determination in the insect order Hymenoptera with specific focus on consequences for mass culturing and biological control aplication. All hymenopterans have haplodiploid reproduction (haploid males from unfertilised eggs, diploid females from fertilised eggs), but with different underlying genetic pathways of sex determination. Single locus complementary sex determination (slCSD) is known from >60 species in different families including the parasitic Ichneumonoidea. Within the family Braconidae slCSD and multi-locus CSD occur in closely related species. Maternal effect genomic imprinting sex determination is only known from the chalcidoid Nasonia. Endosymbionts and genetic elements that alter host reproduction and sex allocation occur widespread among Hymenoptera. They can induce cytoplasmic incompatibility, parthenogenesis, son killing and feminization and could potentially be exploited in biological control.

Evolution and genomic architecture of host specificity in aphelinid parasitoids of aphids

Keith R. Hopper
USDA-ARS, U.S.A.

Assessing the risks of post-introduction evolution in host specificity of parasitoids introduced for biological control is crucial for their safety. Using research on the host specificity in Aphelinus species proposed for introduction against aphids, I discuss three approaches to assessing the risks of post-introduction evolution. The first approach uses phylogenetic and phylogeographic patterns in host specificity. However, studies using this approach showed that host specificity is not phylogenetically conserved and that variation in parasitism among populations within a species suggests adaptation to locally abundant aphids. The second approach is to determine the genetic architecture of host specificity. Interspecific crosses and backcrosses to map quantitative trait loci (QTL) affecting parasitism of a novel host species showed that changes in a few QTL were involved. We are now doing whole genome scans for evidence of local hot spots of differentiation associated with variation in host specificity. The third approach is to determine rate of evolution either in laboratory experiments or after biological control introductions. Laboratory selection for parasitizing a rarely used aphid species gave a more rapid shift in host specificity than expected. Using crosses and backcrosses of high versus low selection lines, we are mapping the QTL involved in the shift. We are also testing whether such evolutionary shifts have occurred in Aphelinus introduced for biological control, and if so, the genomic architecture of such shifts.

Global analysis of the transcriptome of teratocytes reveals its function in development of *Cotesia vestalis* larvae

Xuexin Chen[1], Min Shi[2], Fei Gao[3], Pan Jing[4]
[1]Zhejiang University, China, [2]Zhejiang University, China, [3]Zhejiang University, China, [4]Zhejiang University, China

Teratocytes are cells that originate from the serosa membrane of some hymenopteran parasitoids, which are released into the host haemolymph during the hatching of parasitoids eggs, and develop in the host haemolymph. They are considered to be involved in parasitoid larval nutrient uptake, host immunosuppression and host manipulation. The endoparasitic wasp Cotesia vestalis develops in the hemocoel of larval stage of their host Plutella xylostella with the help of teratocytes. We use the Illumina method to sequence the transcriptome of Cotesia vestalis teratocytes. In a single run, 6,967,361 sequencing reads have been produced, and these reads were assembled into 24,165 unique sequences with a mean size of 208bp. The BLASTx E-value of 79% unigenes ranged from 1.0E-5 to 1.0E-50; the similarity of 44% unigenes against homologous sequences ranged from 60% to 80% and 47% homologous sequences are from Drosophila, Apis, Anopheles and Nasonia species. The putative functions of teratocytes were predicted by gene annotations: (1) nutrient metabolic which consisted of 3 pathways, host fatbody digestion, host trehalose metabolic and nutrient secretion; (2) host regulations which consisted of 6 pathways: host reproductive system regulation, host juvenile hormone regulation, host ecdysone regulation, host chitin regulation, host protease inhibition and host tissue injury; (3) host immunosuppression; (4) toxin-related function; (5) anti-microbial function, and (6) microvilli construction-related function. Funding for this study was provided jointly by the National Science Foundation of China (No. 30871675), Zhejiang Provincial Natural Science Foundation of China (No. Z3100296) and NSFC Innovative Research Groups (No. 31021003).

Combining symbiont-manipulated phenotypes with genomics to unravel genetic bases of parasitoid life history traits

Fabrice Vavre[1], Julien Varaldi[2]
[1]*Biometry and Evolutionary Biology Lab, France,* [2]*Biometry and Evolutionary Biology Lab, France*

Arthropods, among which parasitoid wasps are no exception, are frequently infected by vertically transmitted microorganisms that deeply impact their phenotypes. Different traits can be affected including reproduction, physiology and behavior. These symbiotic manipulations often expand phenotypic variation largely beyond standing nuclear genetic variation. By studying the molecular mechanisms underlying these interactions, we may expect to gain insights on the genetic bases of the affected traits, in a way very analogous to the study of genetic mutants. This framework led us to develop genomic and transcriptomic approaches on two symbiotic systems involving drosophila parasitoids: - In the solitary parasitoid Leptopilina boulardi, the virus LbFV forces infected females to accept to oviposit in already parasitized larvae, a behaviour known as superparasitism. Such manipulation is beneficial to the virus as it benefits from horizontal transmission when parasitoids share the same Drosophila. - In Asobara tabida, removing of Wolbachia leads to copious apoptosis during oogenesis and to a dramatic reduction in egg load. Furthermore, aposymbiotic eggs do not develop, thus rendering Wolbachia necessary for insect reproduction. On these two systems, sequencing of the genome of the symbiont is in progress as well as global transcriptomic approaches comparing infected and uninfected individuals. The first results on these two systems will be presented.

Insect Biological Control

The genetics and genomics of reproductive decisions in parasitoid wasps

David Shuker
University of St Andrews, United Kingdom

Reproductive decisions in insects are of profound interest to evolutionary biologists and ecologists, and are also crucial to attempts to promote or hinder populations of beneficial or pest insects in the wild. In many cases though, our understanding of reproductive behaviour is limited to either the phenotype, or the genetic basis of reproduction in a very limited group of model species (e.g. Drosophila). The advent of high-throughput genomic technologies has the potential to revolutionise our understanding of insect reproductive behaviour, particularly in species with limited genetic resources (i.e. virtually all insects). Here I will describe our on-going work to explore the genetic and genomic basis of reproductive behaviour in the parasitoid wasp Nasonia vitripennis. I will focus on sex allocation and female post-mating behavioural changes, in terms of both traditional quantitative genetic and next-generation sequencing transcriptomic approaches. Our results include the discovery of rather limited male-input into female physiological changes post-mating (contrasting with Drosophila melanogaster for example), along with changes in olfaction- and venom-related gene expression. Oviposition also leaves a footprint in the transcriptome, providing clues as to the genes influencing sex allocation decisions. However, the limitations of such techniques will also be discussed, not least our limited understanding of the function of many insect genes.

Athalia rosae: An emerging genetic model system for sawflies

Masatsugu Hatakeyama
National Institute of Agrobiological Sciences, Japan

Sawflies belong to the primitive Hymenoptera and are known to be pests of cultivated plants, flowers and forests. The turnip sawfly, Athalia rosae, is one of those species, a pest of cruciferous plants, and has unique biological features representing the order, such as parthenogenesis, haplo-diploidy and sex-linked occurrence of meiosis. We developed practical techniques to use this species as a model system: artificial manipulation of egg activation and fertilization, sperm cryopreservation, transposon-mediated germline transformation and RNAi in most developmental stages. Genome sequencing of A. rosae is ongoing and tools especially for analyzing gene function in vivo are prerequisite for utilizing these genomic data. It is thought that genes related to reproduction and development are possible candidates for biological control, for example, for applying to transgenesis-based sterile insect technology. We examined the function of the boule (bol) gene, which encodes RNA-binding protein functioning as a translational regulator, essential for meiosis in male animals. It is intriguing that bol homologues are conserved in the genome of Hymenoptera in which haploid males are devoid of meiosis in spermatogenesis. Some isoforms of the bol transcripts were found in the transcriptome. One was expressed exclusively in the testis and knockdown of bol by RNAi resulted in the absence of mature sperm without affecting any other phenotypes. Knockdown of the presumed downstream target gene, cdc25, showed a similar phenotype. The bol gene is required for progression of maturation division (but not meiosis) in haploid males and its defect leads to male sterility.

Genetics and genomics of fig wasp

Jin-Hua Xiao[1], Da-Wei Huang[2]
[1]*Institute of Zoology, Chinese Academy of Sciences, China,* [2]*Chinese Academy of Sciences, China*

Figs and fig-pollinating wasps are obligate mutualists that have co-evolved for over 60 million years. During the long evolutionary history, the pollinators have evolved many characters adaptive to their lives within the unique compact syconia provided by the figs. We here try to trace these adaptive characters in the genome. We present a draft genome of Ceratosolen solmsi (Hymenoptera: Chacidoidea: Agaonidae) associated with Ficus hispida (Ficus: Moraceae), assembled from Illumina Sequencing reads obtained from all the male offspring of the same grandmother wasp. We used comparative genomic methods to obtain insight into the unique features of the C. solmsi genome. We found that this genome has much fewer genes annotated than its close relative Nasonia vitripennis. Additionally, we identified that C. solmsi harbors the least putative olfactory receptors genes except another insect species obligatory parasitic to human, the body louse. We also studied the genes composition of the immune systems, including the insecticide resistance and dietary detoxification. Putative horizontal transfer elements were also been screened. Some of these and other unique aspects of the fig pollinator genome are likely linked to the peculiar living environment within the compact syconia of this species.

Wratten. Introduction. Get rich or get even? Linking biodiversity and natural pest control

William Emerson Snyder[1], David W. Crowder[2]
[1]Washington State University, U.S.A., [2]Washington State University, U.S.A.

Declining species number (richness) harms ecosystems, and conservation efforts have largely focused on conserving or restoring particular rare species. However, greater disparity in species relative abundances (evenness) might also do ecological harm, which could only be reversed by altering the densities of many species at once. We found that organic agriculture restores even relative-abundances among predator and pathogen biological control agents, dampening pest outbreaks and increasing plant growth. Thus, pesticide-reduction schemes such as organic agriculture provide a particularly promising avenue to restore functional evenness to ecosystems. The restoration of evenness is an achievable goal that can provide substantial ecological benefits.

Flower power? Effects of apple orchard groundcover management on green apple aphids (*Aphis* spp.) their predators and on the canopy insect community

Viktor Marko[1], Gabor Jenser[2], Elod Kondorosy[3], Levente Abraham[4], Klara Balazs[5]

[1]Corvinus University of Budapest, Hungary, [2]Hungarian Academy of Sciences, Hungary, [3]Pannon University, Georgikon Faculty for Agriculture, Hungary, [4]Somogy County Museum, Hungary, [5]Hungarian Academy of Sciences, Hungary

Effects of habitat diversification through ground cover management on green apple aphids [Aphis spp. (Homoptera: Aphididae)], their insect natural enemies and the most abundant canopy insects (Neuroptera, Fulgomorpha, Cicadomorpha, Heteroptera, Coleoptera, Formicidae) was studied in an experimental apple orchard over six years. The abundance of woolly apple aphids [Eriosoma lanigerum (Homoptera: Aphididae)] was assessed in one year when their incidence was high. The habitat diversification was achieved by sowing annual and perennial flowering plants in the alleys of an apple orchard (FLOWER). Plots with weed free bare ground (BAREgr) and with regularly mowed grass (GRASS) served as controls. We found no evidence that flowering herbs sown in the alleys in comparison with grass ground cover or bare ground enhanced the biological control of green apple aphids. However, greater plant coverage in FLOWER enhanced the woolly apple aphid infestation. Increased plant coverage and diversity in FLOWER compared to BAREgr resulted in an increase in numbers of Chrysoperla carnea (Neuroptera, Chrysopidae) adults, leafhoppers and treehoppers, planthoppers, herbivorous (non-apple feeding) beetles, dipterans and parasitoid wasps in the canopy of apple trees. Abundances of these groups in GRASS in most cases were between those in FLOWER and BAREgr. Significantly greater species richness and diversity was found in FLOWER than in BAREgr for most of the studied functional groups although the number of predacious insect species was identical in all treatments.

The biology of *Holepyris hawaiiensis* (Hymenoptera: Bethylidae) parasitoid on *Ephestia cautella* (Lepidoptera: Pyralidae) under laboratory condition

Elahe Sadeghi[1], Valyallah Baniameri[2], Aref Marouf[3]

[1]College of Agriculture, Iran, [2]Iranian Research Institute of Plant Protection, Iran, [3]Iranian Research Institute of Plant Protection, Iran

Abstract The Ephestia cautella is one of the major pests of palm grove and stored date in Iran. In this research, during 2008-2011 in Shahdad, Andijerd, and Kerman province (the south eastern of Iran) Holepyris hawaii is found in high potential in date storage and palm grove. Holepyris hawaii is an ectoparasitoid and gregarious wasp which was collected and reported for the first time in the Middle East. In this essay biology of Holepyris hawaii was studied on larvae of Ephestia cautella which were obtained from the IRIPP, where the culture had been intermittently reared on a semi artificial diet (Marouf et al., 1389) under laboratory conditions (26±2ºC, 65±5RH, and LD14:10). The research duration of the egg, larva, pupa, and the mean total development time for the adult of Holepyris hawaii were 3/07±0/093, 5/06±0/54, 8/13±0/57, and 18/32±0/11 days, respectively.

Seasonal patterns in the biodiversity of natural enemies in California walnut orchards

Nick Mills
University of California, U.S.A.

There has been growing concern that the loss of biodiversity associated with intensification of agricultural production will lead to a reduction in the pest control services provided by the natural enemies of crop pests. It is often considered that natural enemy biodiversity is of greatest importance early in the cropping season in annual crops, but for perennial tree crops biological control services are often required throughout the cropping season. However, little is known of the seasonal pattern of biodiversity of natural enemy species in perennial crops and how this might influence the provisioning of pest control services for foliar pests that are active throughout the season. We monitored the seasonal biodiversity of natural enemies in California walnut orchards in 2010-2011 to determine patterns of change in the overall species richness and diversity of foliar natural enemy species through use of herbivore-induced plant volatiles baited sticky panel traps. We present the seasonal patterns observed for general insect predators and parasitoids, and discuss how these patterns and the observed variation between years and locations are likely to influence the pest control services provided by natural enemies in this important tree crop.

Insect Biological Control

Disentangling the spider's web

James Douglas Harwood
University of Kentucky Lexington, U.S.A.

Agroecosystems, although subjected to monocultural practices that typically suppress arthropod diversity, are surprisingly rich in invertebrate fauna. Temperate agricultural production systems, for example, contain at least 1,500-3,000 species and thus these rather homogeneous crop environments offer resources to arthropod communities that not only allow survival, but foster growth and development of individual populations. Furthermore, the predisposition of many predators to remain in place despite limited resource availability, driven by the inherent risks associated with site or habitat abandonment, facilitates their capacity for pest suppression, potentially impacting prey populations during colonisation. Spiders, dominant predators within such habitats, exhibit many favourable attributes that make them valuable biological control agents. Indeed, their diverse foraging habits, rapid colonisation ability, high levels of site tenacity and, in many cases, voracious appetite for pest species should place them at the forefront of many conservation biological control schemes. This paper will use multi-disciplinary approaches to field ecology to disentangle the complex spider food web in agroecosystems, characterizing the functional role of spiders and examine how in-field diversity impacts biological control services.

Biological control in Kentucky winter wheat: Using molecular tools to assess sustainable management techniques

Katelyn Ann Kowles[1], Douglas Johnson[2], James Harwood[3]
[1]University of Kentucky, U.S.A., [2]University of Kentucky, U.S.A., [3]University of Kentucky, U.S.A.

Aphids are pests of multiple cropping systems, due to the viruses they vector and their rapid rate of population growth. In Kentucky winter wheat, grain aphids (Rhopalosiphum padi, Sitobion avenae) cause substantial yield loss as vectors of Barley Yellow Dwarf virus (BYDV), prompting routine insecticide applications to be applied. Importantly, these aphids are preyed upon by foliage dwelling predators and, when they fall to the ground, epigeal spiders which play a major role in preventing re-colonization of the plant. Consequently, natural weed strips were created to increase natural enemy abundance in the wheat, with the hypothesis that they will promote natural suppression of pestiferous aphid populations. In a multi-faceted approach using spatial, temporal and molecular analysis of predation, this hypothesis was tested with extensive collection of plants, aphids and natural enemies. In the laboratory, samples were indentified and screened for BYDV using enzyme linked immunosorbent assay to quantify the level of infection in the field. Additionally, species richness and diversity counts were conducted to examine the effect that natural weed strips may have on the existing arthropod populations. Results will be discussed in the context of conservation biological control, and how low-cost, low-input manipulations may impact viruliferous aphid populations.

Improved fitness of the parasitoid *Aphytis melinus* receiving sugar subsidies in the field

Alejandro Tena[1], Apostolos Pekas[2], Felix Wackers[3], Alberto Urbaneja[4]

[1]Instituto Valenciano de Investigaciones Agrarias (IVIA), Spain, [2]Universidad Politecnica de Valencia, Spain, [3]University of Lancaster, United Kingdom, [4]Instituto Valenciano de Investigaciones Agrarias, Spain

Many adult parasitoids depend on sugar-rich foods such as nectar and honeydew to meet their energy requirements. Here, we first use HPLC (high performance liquid chromatograph) analyses to assess the sugar reserves (total sugar per parasitoid) and honeydew consumption of individual field collected Aphytis melinus parasitoids, the most successful biological control agent of California red scale Aonidiella aurantii. The number of honeydew producers was also measured when A. melinus were collected. Our data show that A. melinus, whose host does not produce honeydew, fed commonly on honeydew from other abundant hemipterans in spring and summer. However, when the number of honeydew producers decreased, as occurred in fall, less than 20% of A. melinus were found to have fed on honeydew. In fall, the average total sugar content in A. melinus was reduced three-fold. In a second assay, we determine whether the addition of sugar subsidies might improve the fitness and performance of A. melinus when honeydew producers were scarce. For this, we compared the sugar reserves of A. melinus using the HPLC analysis, its population density, parasitism rates on A. aurantii and migration in trees with and without sugar subsidies. Our result show that the number of adult A. melinus per tree, migration, parasitism rates and the number of parasitoids classified as sugar fed (those that had previously fed on sugars) was higher in trees were sugars were added.

Potential predators that may contribute to pests control in future irrigated areas around the newly constructed Hamdab Dam in Northern Sudan

Abdalla Abdelrahim Satti[1], Nazar Abdalla Bilal[2]

[1]Environment and Natural Resources Research Institute, Sudan, [2]Environment and Natural Resources Research Institute, Sudan

The Hamdab (Merowe) dam, which has been constructed recently on the Nile River is located in Northern State, an area lies within the desert arid zone of the Sudan. However, this area is climatically suitable for growing several field and horticultural crops. Therefore, the dam was expected to irrigate thousands of hectares of arable virgin lands along the Nile in the near future. Regrettably, very little research has yet been carried out in that part of the country regarding agricultural pests and their natural enemies. In this study, regular surveys continued for one year (2010/2011) were carried out at three different locations near the dam, where the prevalent predatory species of agricultural pests were reported and counted on certain crops. Hence, the population densities of important predators were compared among the different crops and seasons. Since chemical insecticides are very rarely practiced in the Northern State, numerous species of natural enemies were found flourishing on the studied crops, including mainly, chrysopids, coccinellids, syrphids and spiders (e.g., thomisids, salticids and cob weavers). Consequently, the promising predators reflected the highest prevalence and impacts on major pests were indicated. These predators should receive great attention, as potent natural control agents, whenever agricultural expansion is realized.

Biodiversity and biocontrol: Putting it all together in Asian rice

Geoff M. Gurr[1], Zhongxian Lu[2], Kong L. Heong[3], David J. Perovic[4], Pingyang Zhu[5]

[1]Charles Sturt University, Australia, [2]Zhejiang Academy of Agricultural Sciences, China, [3]International Rice Research Institute, China, [4]Economic Development and Innovation, Australia, [5]Zhejiang Academy of Agricultural Sciences, China

This presentation will provide an overview to laboratory and field results from a three-year, multi-country assessment of the efficacy of ecological engineering for enhancing biological control of rice planthopper pests. Laboratory studies focussed on the response of key parasitoids Anagrus nilaparvatae and A. optabilis and the important predatory mirid Cyrtorhinus lividipennis to potential nectar plants for use on the bunds around rice fields. Y-tube olfactometer studies with sesame, Impatiens balsamena, Emilia sonchifolia, Tagetes erecta and Emilia sonchifolia indicated that sesame most consistently proved attractive to adult natural enemies, maximised longevity, enhanced parasitism or predation of brown planthopper eggs and reduced handling time. Sesame also had the practical advantages of being long-flowering and valued by farmers as a secondary crop. Field experiments in China, Vietnam and Thailand showed that using locally appropriate nectar plants (commonly sesame) on bunds led to natural enemy numbers and diversity being markedly enhanced and good control of rice planthoppers under conditions of greatly reduced insecticide inputs. Rice grain yields were maintained and economic analysis suggest this ecological engineering approach to be favourable to conventional farmer practice. Furthermore, frog numbers were increased, suggesting a wider benefit to biodiversity. Up-scaling of ecological engineering for rice is now underway in each country, funded by significant funding by the respective Governments for promotional materials and demonstration sites.

Niche engineering reveals complementary resource use among predators

David Crowder[1], Jake Gable[2], Tobin Northfield[3], Shawn Steffan[4], William Snyder[5]
[1]Washington State University, U.S.A., [2]Washington State University, U.S.A., [3]WSU, U.S.A., [4]Washington State University, U.S.A., [5]Washington State University, U.S.A.

Greater resource use by diverse communities might result from species occupying complementary niches. Defining niches can be challenging, however, due to the difficulty in relating differences between species in particular traits to their use of complementary resources. Here, we overcame this obstacle by exploiting plastic foraging behavior in a community of predatory insects. These predators complemented one another by partitioning foraging space, with some species foraging primarily along leaf edges and others at leaf centers. Indeed, on intact leaves, edge- and center-foraging predators combined to kill more prey than any single predator species could by itself. These emergent diversity effects, however, disappeared on plants damaged by the caterpillar Plutella xylostella. Caterpillar chew-holes brought edge habitats to the center of leaves, such that all predator species could attack aphids anywhere on the plant. With spatial niche differences diminished, there were no benefits of predator diversity; the most voracious single predator species killed the most aphids. Thus, caterpillar herbivory determined whether multi-predator-species effects reflected complementarity or species' individual impacts. Our study provides direct evidence for a causative relationship between niche differentiation and increased resource consumption by diverse communities, as revealed by ecological engineers that homogenize the foraging environment.

Agricultural intensification drives landscape effects on host-parasitoid interactions in agroecosystems

Mattias Jonsson[1], Hannah L. Buckley[2], Bradley S. Case[3], Steve D. Wratten[4], Roddy J. Hale[5], Raphael K. Didham[6]

[1]Swedish University of Agricultural Sciences, Sweden, [2]Lincoln University, New Zealand, [3]Lincoln University, New Zealand, [4]Lincoln University, New Zealand, [5]Lincoln University, New Zealand, [6]The University of Western Australia, Australia

Agricultural land use threatens biological control by natural enemies because of simplification of habitat structure and intensification of disturbance and agrochemical inputs. Here, we disentangle the mechanisms driving landscape-scale effects on host-parasitoid interactions by taking advantage of a landscape modification gradient in which the diversity of habitat types and annual crop cover in the landscape were uncorrelated. We quantified herbivore densities and parasitism and hyperparasitism rates on two important crop pests across 30 landscapes. We used structural equation modelling (SEM) to test whether land-use intensity (insecticide application and habitat disturbance) or resource availability for parasitoids (floral resources and alternative host plants) were mediating the effects of habitat diversity and annual crop cover in the landscape. Rates of primary- and hyper-parasitism of aphids and primary parasitism of P. xylostella decreased with increasing annual crop cover, whereas decreasing habitat diversity in the landscape had little effect on parasitism rates. These effects were mediated almost entirely by greater habitat disturbance and greater frequency of insecticide application, rather than by changes in resource availability. Our work suggests that increased land-use intensity (e.g. higher insecticide inputs and greater levels of disturbance associated with increasing area of annual crops) has been underestimated as a driver of landscape effects on host-parasitoid interactions. These findings have important implications for the maintenance of biological control. The promotion of low-intensity farming practices that limit the extent and frequency of agrochemical inputs and habitat disturbances will be essential for the maintenance of effective biological control by parasitoids in agroecosystems.

Agricultural policy-induced landscape changes: Effects on carabid abundance and their biocontrol potential

Pavel Kindlmann[1], Olga Ameixa[2]
[1]*Czechglobe, Czech Republic,* [2]*Czechglobe, Czech Republic*

Biodiversity plays a key role in management of most agroecosystems, and potentially can affect biological control of insect pests. However, diversity of crop food webs can be negatively affected by the recent crop management practices, including use of synthetic herbicides and/or artificial fertilizers (especially nitrogen), which can alter abiotic and biotic components of the agroecosystems. We studied the relative importance of (1) nitrogen input, (2) pesticide use and (3) environmental factors (field size, landscape diversity, neighbouring cultures and habitats, altitude) on ground beetle community structure, diversity (Shannon-Wiener index) and abundance in 150 wheat fields or parts thereof, which belong to 30 farms over a period of 2 years, using pitfall trapping. In each year, two collections were made, one in spring and one in summer. This enabled us to include seasonal and annual variations. The results are of strong practical importance, as ground beetles are supposed to have a potential role in suppression of cereal aphids; the latter were reported to be responsible for up to 15% decrease in yield and aphid outbreaks are related with agricultural intensification.

Economic impact of termite pests and current control practices

Michael K. Rust
University of California Riverside, U.S.A.

Drywood and subterranean termites are the number one structural pest in the US with an economic impact of nearly $ 3 billion annually. Subterranean termites represent about 75% of this figure and their impact is more widely distributed than drywood termites. The primary incidence and major damage caused by drywood termites being restricted to Arizona, California, Florida, and Texas. However, the urbanization of the desert southwest has resulted in increased termite activity. Invasive species pose a special problem for the Gulf States and Florida. The two primary strategies for controlling drywood termites are entire structure treatments and localized treatments. Fumigation or heat treatments are the two viable options for treating the entire structure. Of the various localized treatments, only the localized chemical treatments have shown much promise for remedial control. Injections of spinosad, fipronil, thiamethoxam, and boric acid dust into galleries have provided excellent control and are promising as localized treatments. For nearly 60 years, the principle method of remedial control of subterranean termites has been the application of pesticides to soil to provide a chemical barrier. In the last decade, soil toxicants with delayed toxicity and low repellency have replaced the classic repellent chemistries such as the pyrethroids for remedial control. With the advent of dose independent chitin synthesis inhibitors such as hexaflumuron, noviflumuron, and diflubenzuron, baiting technology has dramatically expanded especially for subterranean species that are aggressive foragers.

Termite pest species and their control options in Japan

Tsuyoshi Yoshimura[1], Kunio Tsunoda[2]
[1]Kyoto University, Japan, [2]Kyoto University, Japan

Of 23 termite species distributed in Japan, only 5 species are recognized as pests. They are Reticulitermes speratus, R. kanmoensis, Coptotermes formosanus, Cryptotermes domesticus and Incisitermes minor: three subterranean and two dry-wood species. At present, more than 99% of termite damage in Japan is attributed to subterranean species, however, dry-wood termite damage, particularly by I. minor, is now increasing. These days the termite control market in Japan is estimated as 70 billion JPY (= 900 million USD). Similar to the other countries with subterranean termite problems, soil/timber treatments by liquid formulations with non-repellent active ingredients are the most popular method. In Japan, the soil treatment is basically conducted inside the foundations, and the perimeter treatment is not common due to environmental concerns. Construction timbers up to one meter from the top of the foundation are normally treated by brushing/spraying. Concern about the leaching-out from the treated timbers restricts the use of borates. Pressure-treated sills are commonly used in residential houses. The testing methods of chemicals against termites are standardized by the JIS K-1571(2010). Baiting and the installation of physical barriers are not yet widely used in Japan, mainly due to their costs. Governmental policy for promoting the construction of long service-life buildings, for both, residential houses and also public buildings, is now enhancing the development of technologies for inspection/diagnostic systems of termite infestations. Since fumigation of buildings is difficult in Japan, finding novel control systems against I. minor will be the big issue in the near future.

Termite pests and their management in Southeast Asia

Chow-Yang Lee
Universiti Sains Malaysia, Malaysia

Termites are an important group of urban insect pests in South East Asia. In Malaysia, Coptotermes gestroi accounted more than 85% of the total damages of buildings and structures, and similar observations were recorded in Thailand, Indonesia and the Philippines. It is also common to find several termite pest species co-existing and infesting buildings and structures. In Malaysia, other species that can be readily found in- and around buildings and structures, including C. curvignathus, C. kalshoveni, Microcerotermes crassus, Macrotermes gilvus, Macrotermes carbonarius, Odontotermes spp., Schedorhinotermes spp and Microtermes pakistanicus. For drywood termites, Cryptotermes cynocephalus is the common species in Malaysia and Indonesia. In Thailand, Microcerotermes crassus is gradually becoming an important pest species in buildings and structures built on former rice field in suburbia. In the Philippines, M. gilvus, Microcerotermes losbanosensis and Nasutitermes luzonicus were most prevalent after C. gestroi. For drywood termite, Cryptotermes thailandis occasionally spotted in wooden houses and furnitures mostly in the southern part of the country both inland and along the coastline or on the islands. In the Philippines, the most important drywood termite species is Cryptotermes dudleyi. In South East Asia, it has been observed that baiting activity has increased the prevalence of secondary species in buildings and structures.

Termite control practices and recent IPM project in mainland of China

Sujin Tan
Chengdu Institute of Termite Control, China

There are about 10 species of harmful termites in China. Most of them distribute in the south of China. BC 220 years , termite control was recorded in some classical works. But before 1950, termite control area was very small and the means rarely . During recent decades, great progress has been made whether in the control area or the control theory and technology. Especially, since July 2006 , an IPM demonstration project entitled "Demonstration of Alternatives to Chlordane and Mirex in Termite Control" by GEF fund supporting, WB and Chinese government participating has been carried out under the frame of the Stockholm Convention on Persistent Organic Pollutants (POPs). By December 30, 2011, three demonstration provinces have installed 694,100 in-ground(IG) and 151,500 above-ground(AG) bait systems with preventive treatment covering 77.2372 million square meters and remedial treatment 3.805 million square meters, relating to residential buildings and all types of architecture for purposes of culture, public health and historic heritage. A significant effect of control has been shown after use of the monitor-controlling system. By the use of this system ,the termite threat has been eliminated from those demonstration items and the use of chemical insecticide has been reduced greatly.Through this project, we have completely eliminated the use of chlordane and Mirex in demonstration provinces and got a lot of useful experience not only in management and technology but also in understanding IPM theory on termite control in China.

Termite pests and their control in Taiwan

Hou-Feng Li
Academia Sinica, Taiwan

Five of the 17 recorded termite species in Taiwan are considered as pests of wooden structures and wood products. Two subterranean termites, Coptotermes formosanus Shiraki and Coptotermes gestroi (Wasmann), are the major pests and responsible for > 87% of termite infestations in urban area. Both species are most found at low land area < 500 m. C. formosanus is distributed throughout Taiwan, but C. gestroi is restricted in southwest. Another subterranean termite, Reticulitermes flaviceps (Oshima), occasionally attacked manmade structures, resulting in < 1% infestations. R. flaviceps are commonly found in mountainous areas and lowland of northern Taiwan. The drywood termite, Cryptotermes domesticus (Haviland), is responsible for 6% infestation mainly in southern Taiwan. The fungus growing termite, Odontotermes formosanus (Shiraki), is the most common termite species in Taiwan distributed from lowland up to 1,200 m altitude. O. formosanus is a minor urban pest contributed 6% structural infestation but a major agricultural and forestry pest. Currently, 116 pesticide products are labeled for termite control in Taiwan and nine of them were specialized for this purpose. Eight active ingredients including boric acid, hexaflumuron, noviflumuron, fipronil, imidacloprid, bifenthrin, cypermethrin, and permethrin are used in the nine specialized termiticide products. Organophosphates and pyrethroids are used primarily in the non-termite-specific pesticides. Based on the questionnaire survey in 2009, the liquid pesticide with fipronil as the active ingredient was used in 75% of all cases and termite bait containing hexaflumuron was employed in 20%.

Non-repellent termiticides: Development, key features, efficacy and control

Raj Saran
DuPont, U.S.A.

In past decade, non-repellent termiticides have emerged as a popular treatment alternative in post-construction infestations. Most of these termiticides have performed very well in the field compared to the repellent termiticides used in the past. The superior performance of these new generation termiticides is attributed to their non-repellency, delayed toxicity and their ability to be transferred from exposed to unexposed worker termites. However, researchers have demonstrated that several factors such as dose, period of exposure, and mode of action of the insecticides also play a significant role in the efficacy and horizontal transfer of non-repellent termiticides. In addition, all the termiticides are applied to the soils and therefore soil physical and chemical characteristics also have an effect on the bioavailability of these termiticdes to the termites tunneling in treated zones. Soil types may also affect degradation and movement of these termiticides in the soil. Thus, the efficacy and performance of these termiticides should be studied in relation to all the above mentioned factors to know their key attributes.

Development of baiting as a method to control subterranean termites

Michelle Smith[1], Leng Choy Lee[2]

[1]Dow Agrosciences LLC, U.S.A., [2]Dow Agrosciences LLC, Malaysia

As early as the 1960's a "bait method of control" for subterranean termites was discussed in scientific literature. The concept described at the time was to use toxicant-impregnated wood blocks to suppress populations of pest termite species in the field. In the years since then, considerable research has been conducted to investigate potential active ingredients for termite bait, including pathogenic fungi, metabolic inhibitors such as sulfluramid, chitin-synthesis inhibitors such as diflubenzuron, lufenuron, and hexaflumuron, and even fipronil and encapsulated permethrin. Additional work has been published on associated stations, matrices, sensors and attractants. Focused research efforts resulted in the first termite baiting system being commercially introduced in 1995. Termite baiting systems now represent a substantial portion of the termite control market in the USA and a growing proportion of the termite control market globally, with research continuing to refine many of the elements earlier defined.

IPM area-wide projects and population dynamics of subterranean termites

Nan-Yao Su
University of Florida, U.S.A.

With the availability of commercial baits capable for eliminating colonies of subterranean termites, several area-wide projects have been attempted. Most of these projects follow the conceptual framework of termite IPM (Integrated Pest Management) as suggested by Su & Scheffrahn (1998), i.e., to manage termite populations via colony elimination by using less persistent and less toxic insecticides at smaller quantities. Area-wide projects in the US and the termite IPM project implemented in three provinces in China will be discussed. One vital issue for area-wide projects is the recovery process of subterranean termite populations in target areas following the total elimination of all detectable colonies. In the 34-acre Armstrong Park of New Orleans, Louisiana, activity of the Formosan subterranean termite reached a full recovery 5-6 years after all detectable colonies had been eliminated. The Park was repopulated by three types of colonies, i) small colonies that were undetected during the initial elimination attempt (concealed colonies), ii) incipient colonies initiated by alates flew in after the total elimination, and iii) established colonies neighboring the Park.

A simulation study on the territorial competition of subterranean termites

Wonju Jeon[1], Sang-Hee Lee[2]

[1]National Institute for Mathematical Sciences, Republic of Korea, [2]National Institute for Mathematical Sciences, Republic of Korea

The foraging territories of 2 subterranean termites, Coptotermes formosanus Shiraki and Reticulitermes flavipes (Kollar), were simulated using a two-dimensional model to explore how territorial competition changes with 4 variables characterizing the formation of territory: the number of primary tunnels, N_0; the branching probability, P_branch; the number of territories, N; and the blocking probability, P_block. The blocking probability P_block quantitatively describes the likelihood that a tunnel will be terminated when another tunnel is encountered; higher P_block values indicate more likely termination. We defined a territory as a convex polygon containing a tunnel pattern and explored the effects of competition among termite colonies on territory size distribution at steady state attained after sufficient simulation time. At the beginning of the simulation, N = 10, 20, …, 100 initial territory seeds were randomly distributed within a square area. In our previous study, we introduced an interference coefficient γ to characterize territorial competition. Higher γ values imply higher limitations on network growth. We theoretically derived γ as a function of P_block and N. In the present study, we considered the constants in γ as functions of N_0 and P_branch so as to quantitatively examine the effect of tunnel structure on territorial competition. By applying statistical regression to the simulation data, we determined the generalized γ functions for both species. Under competitive conditions, territory size is most strongly affected by N_0, while territorial competition is most strongly affected by N, followed by P_block and N_0.

Community-based termite baiting projects in California

Vernard Richard Lewis
University of California Berkeley, U.S.A.

Community-based termite baiting projects in California. Vernard R. Lewis University of California, Berkeley Department of Environmental Science, Policy and Management137 Mulford Hall #3114 Berkeley, CA 94720-3114. Abstract ? I will review several community-based termite baiting projects for Northern and Southern California. All studies involved species of subterranean termites found in California, primarily the Western subterranean termite, Reticulitermes spp. The study areas were considerable in size, ranging from several to more than 36 ha. For the Northern California site, 550 in-ground bait stations were installed and monitored around thirty-three buildings. The Southern California was considerably larger; over 7,300 in-ground bait stations were installed and monitored around 140 structures. Discovery time and percentage of stations hit for in-ground stations by foraging termites was typical for California's Mediterranean climate, several months and 12% during the first year. However, the use of ancillary stations, applications of sugar water, and control service visits to monitor for termite foraging and feeding achieved higher station hit rates and bait consumption. The disappearance of termites from stations and the drastic reduction of consumer complaints were consistent and supportive of colony elimination for many colonies at and surrounding both sites. The use of area-wide management practices that includes monitoring and baiting is a strategy that is consistent with Integrated Pest Management principles, while also providing the framework and mechanism for termite remedial control and prevention. Lastly, significant savings to the environment can be realized by lessening the need for high volume applications of liquid termiticides

Community-based subterranean termite projects in New Orleans, Louisiana.

Claudia Riegel[1], Edgar Bordes[2]
[1]City of New Orleans, United States Minor Outlying Islands, [2]City of New Orleans, United States Minor Outlying Islands

The Formosan subterranean termite (FST), Coptotermes formosanus Shiraki (Isoptera: Rhinotermitidae) is a destructive, introduced pest species indigenous to Southeast China. This termite has become established in New Orleans and it has supplanted native subterranean termites as the primary structural pest species of structures and trees. In 1998, an area-wide termite project was initiated to reduce the numbers of FST in the French Quarter. This project was the first and largest area-wide termite management program of its kind. This program has saved the French Quarter including its historic structures and trees from devastation by the Formosan subterranean termite. Among the project's many goals was obtaining and utilizing basic FST biological information to maximize control efforts. In this vein, the program has developed novel termite detection tools which are now used by the pest control industry. Public and industry education was a major component of the project. People continue to unwittingly transport this devastating termite to new areas each year. Public awareness and education is the first step to stopping the spread of this invasive species. Operation FullStop technologies, techniques, and educational materials are being utilized nationwide by the pest control industry. Operation FullStop was a unique and successful partnership among the federal government, local government, universities, private industry, and non-profits resulting in great economic benefit for the general public.

From research to end user: Community-based termite management in Chile

James Lawrence Smith
Bosques Cautin, Chile

Area wide termite management research in Santiago, Chile began in 1999. Studies to show the effect of Hexaflumuron termite bait were carried out in a 5 hectare residencial setting in the community of Cerro Navia. These studies verified the effectiveness of the Sentricon baiting system for the management of Reticulitermes flavipes foraging populations. The study showed that intense baiting in a limited number of bait station clusters eliminated pest activity at distances up to 60 meters. These findings lead to the development of a low cost area-wide protocol for baiting subterranean termite populations, especially for use in low income settings. After three years of field research, termite elimination projects were carried out in various municipalities within Santiago and Chile´s fifth region. Initial field baiting was performed by trained pest management professionals. These same professionals trained municipality staff in the biology, behavior and management of subterranean termites. The baiting system was then made available to the municipalities for use by their own trained employees, within their integrated pest management programs. These efforts have been extremely cost effective, have eliminated termite foraging populations and the use of toxic chemical barriers.

DNA genotyping for assessment of treatment success in area-wide termite control

Claudia Husseneder[1], Dawn M. Simms[2]

[1]Louisiana State University Agricultural Center, U.S.A., [2]Louisiana State University Agricultural Center, U.S.A.

The cryptic life style of subterranean termites makes direct observation of colony numbers, sources of alates and treatment success difficult. Microsatellite genotyping, i.e., the analysis of repetitive sequences in the genome that are variable in length and are inherited in a Mendelian fashion, provides a method to characterize termite colonies and assess treatment success on the colony and population level. This talk presents how DNA profiles were used in several model studies of the Formosan subterranean termite (Coptotermes formosanus) in New Orleans, Louisiana, USA. By assigning termites to colonies via their DNA profiles much needed information was gained about size and location of foraging areas of termite colonies, colony numbers, colony movement, and breeding system of colonies. Using DNA profiles it was determined that the treatment program truly eliminated all treated colonies regardless of the size of their foraging area and their breeding system. Since New Orleans has high termite pressure, termites re-infested the study area again after treatment. DNA profiles revealed that the re-infesting termites did not originate from the previously treated colonies, i.e. treatment worked but other colonies move into vacated areas. Light-trapping of alates and relatedness calculations were used to estimate the numbers of colonies contributing alates to termite swarms and to monitor the decline in the number of mature colonies in the area-wide treatment program in New Orleans.

The mechanics of tunnel excavation in subterannean termites, a preadaptation to fungal gardening.

Paul Michael Bardunias[1], Nan-Yao Su[2]
[1]*University of Florida, U.S.A.*, [2]*University of Florida, U.S.A.*

Since Grasse's groundbreaking work (1959), construction and excavation in termites and ants has been thought to be coordinated through a system of threshold responses to pheromones. Recent studies on subterranean termites suggest pheromones may play no direct role in the removal of soil, relegating their function to recruitment. In this new model, tunnels are viewed as extensions of the termite phenotype and serve as an organizing factor, limiting movement to specific vectors, and providing unambiguous starting and ending points. Tactile information and traffic density provide the template coordinating the labor of excavators. When tunnels are too narrow for the number of termites attempting to gain access to soil at the tunnel's end, a queue forms and termites take soil from the tunnel walls wherever they are held up. Widening of the tunnel end can lead to bifurcation, while depressions in tunnel walls left by periodic widening of tunnels act as cues for future branching. Excavated soil is deposited along the walls and inside depressions, acting to narrow tunnels and inhibit branching. At food sources, termites transition from excavating through soil to excavating into wood. The tailings, small wood fragments, are deposited along tunnels in the same manner as soil. The result is that tunnels near food sources are lined with wood fragments. This sequestered wood, subsequently covered in a fecal envelope, is a unique microhabitat, and may be the route of fungal invasion that was a necessary precursor to the type of fungal gardening seen in more derived termite species.

Termite movement efficiency in their tunnel galleries

Seungwoo Sim[1], Sang-Hee Lee[2]

[1]National Institute for Mathematical Sciences, Republic of Korea, [2]National Institute for Mathematical Sciences, Korea, Republic of

Subterranean termite, Reticulitermes speratus kyushuensis (Isoptera: Rhinotermitidae), excavate complex tunnel networks below the ground for foraging. The tunnels are either curved or meandering. In the present study, we explored how the time spent inside a tunnel changes in accordance with the degree of tunnel curvature. To do so, we constructed artificial tunnels with different curvatures in acryl substrates. The tunnel was 5 cm in length with widths of W (W = 2, 3, or 4 mm), and the distance between the 2 ends of the tunnel was D (D = 2, 3, 4, or 5 cm). A higher value of D means a lower curvature. We measured the time (τ) taken by a termite to pass through the tunnel. In the case of W = 2 mm, the values of τ were statistically equal for D = 2, 3, or 4 cm, while that for D = 5 cm was significantly lesser. In the case of W = 3, τ was statistically more for D = 2 and 3 cm than it was for D = 4 and 5 cm. For W = 4, τ was statistically equal for D = 2 and 3 cm, while τ for D = 4 cm was relatively shorter. Interestingly, the value of τ when D = 5 cm was statistically the same when D = 3 or 4 cm. These resulted from 2 types of termite behavior, biased walking and zigzag walking.

Pest of stores and stored products-an archaoentomological perspective

Eva Panagiotakopulu
University of Edinburgh, United Kingdom

The history of pests of stored products provides insights into the origins of storage and agriculture as well as trade and changes in economy. The flightless grain weevil, Sitophilus granarius spread from the Fertile Crescent with the origins of agriculture to the eastern Mediterranean and into Central Europe. Later, it was carried to the northern margins of the Roman Empire and beyond with the Vikings to the North Atlantic islands. It provides an example of the biogeographic implications of introductions of pests and their impact on early agriculture and trade. Palaeoentomological work from archaeological sites in the Eastern Mediterranean allows some understanding of processes involved and information on the early dispersal of storage pests, which included Rhyzopertha dominica, Tribolium castaneum, and Lasioderma serricorne among others. Potentially these early Neolithic and later sites will chart the progress of introductions and routes of dispersal. The process of introductions of pests in the North Atlantic, in particular to areas where there was no cereal cultivation is interweaved with European colonization of new lands and Hanseatic trade and provides some understanding behind the processes of species becoming cosmopolitan. From Northern Europe to the North Atlantic Islands and Canada this is a story of overcoming biogeographic barriers, accidental introductions and some improbable immigrants which accompanied people on most of their journeys.

Evolution of grain pests

Hiroki Obata
Kumamoto University, Japan

Employing a new examination method "impression method" which is the way to recover the living things from prehistoric potsherds have been giving us a lot of evidences on the history of plant utilization in Japan since 2005. One of the great discoveries deserves our attention is maize weevil, Sitophilus zeamais Mots.. In recent Japan we have two Sitophilus species which are S. oryzae L. and S. zeamais which are harmful insects infesting stored grains, mainly rice. Before our new discovery at Sanbonmatsu Site it had been believed that two species may have been diffused by the spread of rice agriculture in East Asia and have intruded into Japan accompanied with rice cultivation from Korea. However the Sanbonmatsu maize weevils dated back to ca. 10500 cal BP. In that time there was neither domesticated rice nor wild one in Japan. Therefore we estimated that maize weevil might be indigenous insect living in Japan since over 10000 years ago and has infested the stored dry seeds in Jomon villages, for example, acorn, chestnut, or legume and attributed it the world' oldest house pest. This suggests we must reconsider previous scenarios for the evolution and propagation of grain pest weevils, especially in eastern Asia. In order to study the problem we must seek the archeological evidence for Sitophilus species in Korea and China in further study. We believe future interdisciplinary collaborations among geneticists, entomologists, and archaeologists in the East Asia will solve the problem.

Invasive and synanthropic - updated aspects on the natural and cultural history of the webbing clothes moth *Tineola bisselliella* (Lepidoptera: Tineidae)

Rudy Plarre
Federal Institute for Materials Research and Testing, Germany

It is generally accepted that the natural habitats of most pest insects can be found outside the synanthropic environment in layers of leaf litter, under bark, as well as in rodent or bird nests. Indeed, most of the common pests have been reported as being facultative nidicolous. Therefore infestation of commodities by pest insects out of these reservoirs is one considerable possibility. However, the likelihood of a pest´s occurrence and survival out-doors largely depends on its ecological potential and competitiveness against other species of the same ecological guild. Some pest species are rarely found in wild habitats, especially in those regions where they are not native and where they have been introduced by man. The fabric pest Tineola bisselliella serves as a good example. Most likely originating in Southern Africa this insect was introduced into Europe probably not earlier than the late 18th century. Being more tolerant to dry environments than other fabric pests its economical importance increased during the 20th century when in-door climates changed because of central heating systems. Its occurrence in out-door natural habitats must be regarded as accidental. Reported founds of webbing clothes moth larvae in bird nests e.g. have been largely overstated in the literature. This paper will try to reconstruct the natural and cultural history of T. bisselliella by summarizing autecological, behavioral, and archeological data in combination with critically analyzed published faunistic records. It will be argued that the webbing clothes moth is a true synanthropic species in most parts of the world.

The practicality of using molecular techniques for identification of stored-product insect pests

Zhihong Li[1], Bngyi Cui[2], Qianqian Yang[3]
[1]China Agricultural University, China, [2]China Agricultural University, China, [3]China Agricultural University, China

Proper identification of species is significant for insect pests monitoring and management, quality control of stored products, and quarantine of imported grains. Molecular techniques based on DNA analysis are regarded as the rapid, viable, and economical methods of species identification which overcoming the non-adult and non-complete sample of individual insect and the lack of available taxonomic expertise. In recent years, different molecular techniques were employed to characterize and identify the species of stored insect pests, including DNA polymorphism assays, DNA barcoding, and species-specific primer. In this review, we summarized the studies and applications of molecular techniques to identify the common stored product pests. DNA polymorphism assays, such as RAPD, RFLP and DNA fingerprinting technique were widely used in rice weevil, maize weevil, saw-toothed grain beetle and psocids. DNA barcoding which based on the sequence of mitochondrial 16S rDNA, COI, and nuclear ITS rDNA was studied especially for stored psocids identification. Species specific primer made the stored-product insect pests identification more timesaving and inexpensive, e.g., the multiplex species specific PCR was developed to identify several psocid species, and the real-time PCR served as a rapid and accurate detection method of granary weevil and Indian meal moths. For the molecular identification of stored-product insect pests in the future, more international collaborations are expected.

Use of molecular methods for species diagnostics and to identify dispersal patterns of stored-product insects

Katarina Mikac
University of Wollongong, Australia

For the past decade my research group have used a range of nuclear and mitochondrial molecular markers to investigate the genetic diversity and global dispersal patterns of stored product pests e.g. booklice Liposcelis bostrychophila and L. decolor and the warehouse beetle, Trogoderma variable and agricultural pests e.g. western corn rootworm Diabrotica virgifera virgifera and the apple codling moth Cydia pomonella. Although a range of molecular markers have been used to study these species, similar genetic patterns between the species investigated have been found. In general for these pests the genetic diversity and structure is lower in their invaded range compared to their native range despite gene flow or dispersal being unrestricted and multidirectional. Genetic diversity is usually lower in introduced populations; however, diversity loss is mitigated by multiple introduction events that ultimately strengthen the diversity of the invaded populations. This has significant ramifications for control programs especially if resistant alleles are introduced into areas where they were not previously found. In this presentation I will present four short case studies of the invasive insects that I have studied to highlight how we have come to understand their invasion genetics through the use of molecular markers. I will discuss how global commodity trading has facilitated multiple introductions of pest insects and removed barriers to their dispersal. Also I will discuss which molecular markers are helping to inform quarantine diagnostics and integrated pest management practises.

Recent advances of stored-product psocid research in China

Dan-Dan Wei[1], Wei Dou[2], Jin-Jun Wang[3]
[1]Southwest University, China, [2]Southwest University, China, [3]Southwest University, China

In the last two decades, psocids (Psocoptera) have become a serious problem in grain storages in China. To date, 1,588 species in 166 genera and 27 families and 3 suborders of psocids are known, whereas, only 27 species were described in the genus Liposcelis from China. Numerous paperss on psocid bionomics, physiology and biochemistry, control measures, and molecular biology have been published. The main differences about biochemical and toxicological characteristics of detoxification, target enzymes and energy sources were clarified among some psocid species. Some detoxifying enzymes (GSTs) and target enzymes (AChE) were purified in psocids and the biochemical and toxicological characterizations of these purified enzymes from different resistant strains and field populations were systematically analyzed. At molecular levels, the research mainly includes molecular identification of similar species, resistance mechanisms, population genetic structure, and detection of symbiotic bacteria. Gene cloning of detoxification and target enzymes and further mRNA expression level and heterogeneous expression of these functional genes were carried out. A detailed understanding of psocid gene flow patterns and the resultant genetic structure among populations within China and all previous researches were useful to understand the formation of resistance mechanisms of psocids to insecticides. These results not only fastened the acquaintance of psocid molecular toxicology and enriched the content of evolution and genetic variation, but also contributed to development of a molecular diagnostic technique for psocid resistance in the field and paved the way for designing new insecticides and developing new strategies for pest management.

Recent advances in development of attractants for stored-product insects

Thomas Wesley Phillips
Kansas State University, U.S.A.

Pheromones and other attractants are widely sued for IPM stored-product pests, mainly through use of traps to detect and estimate insect numbers for management decision-making. Pheromone-baited monitoring traps are routinely used for stored-product moths such as Plodia interpunctella and Cadra cautella, the cigarette beetle, the warehouse beetle and the Tribolium flour beetles. A recent breakthrough in pheromone-based suppression was the registration of a common moth pheromone for mating disruption if Indianmeal moth and its relatives. Mating disruption shows promise for control of the cigarette beetle. The male-produced aggregation pheromone system of Tribolium castaeum was recently elucidated further with regard to stereochemistry of the chiral pheromone, and this may lead to improved trapping of this pest. A food-based pheromone lure was developed for storage moths that has been used with some success for monitoring and possibly control in the US. Cheese mites, Tyrophagus putrescentiae, are serious pests of dried meats, cheeses and other animal-food products. Recent work on semiochemicals for deterring mites from infesting foods, and also work on mite attractants for use in monitoring mites in traps, is underway. Thus semiochemical-based methods have potential to contribute greatly to IPM for stored-product pests, and population suppression without routine use of fumigants and residual insecticides is possible.

Mating disruption for control of stored product insect pests

Christos Athanassiou
[1]*University of Thessaly , Greece,*

During the last decades, mating disruption has been successfully evaluated for the control of numerous field pests, especially Lepidoptera. However, until recently, the data available for the application of mating disruption is stored product pests were relatively few, and mostly restricted to laboratory studies. Nevertheless, the stored-product ecosystem can be regarded as an ideal environment for the application of this technique for two basic reasons. First, it is an enclosed environment, which means that immigration of mated females from outside is rather limited, at least in comparison with field pests. Moreover, most stored product Pyralidae respond successfully to one single pheromone, (9Z,12E)-tetradecadienyl acetate (known as TDA or ZETA), which means that the control of many species with only one component is feasible. This feasibility was tested during the last five years in Europe and the US, with various and often contradictory results. A series of field trials, carried out between 2007 and 2012, indicate that pheromone-based control of stored product Pyralidae is effective, and can be used in various types of facilities and conditions, without loss in efficacy. Currently, several mating disruption formulations are commercially available in many parts of the world, but additional testing to standardize its use is needed in some cases. Apart from the "classical" mating disruption formulations, the use of "auto-confusion" with TDA was also evaluated, and recently commercialized. Overall, the use of mating disruption for the control of stored-product Pyralidae is an effective, viable and non-toxic method over the use of traditional pesticides.

Synthetic pheromone-based mating disruption for cigarette beetles: Present and future perspectives

Rizana Mohamed Mahroof
South Carolina State University, U.S.A.

Each year, the cigarette beetle, Lasioderma serricorne (Coleptera: Anobiidae) cause significant damage to multi-billion dollar food and feed industries nationwide. These beetles are pervasive and commonly associated with flour mills in the United States. A non-chemical alternative in managing L. serricorne is the application of mating disruption, in which an unnaturally high level of synthetic sex pheromone is released in an area that results in males failing to locate females with an ensuing population crash. Using synthetic anhydroserricornin and serricornin, the sex pheromone of L. serricorne, mating disruption trials were conducted in selected food and feed processing facilities in South Carolina during 2010 and 2011. Mills subjected to mating disruption trials were monitored using oviposition cups and pheromone traps lured with monitoring pheromone. Immediately after deployment of mating disruption dispensers, population levels indicated a "significant trap shut down" effect in treated facilities. A significant reduction was observed in number of adults beetles caught in the traps eight weeks before and after treatment in year 2010 and 2011. Adults emerged from oviposition cup also decreased soon after mating disruption treatment. Preliminary field studies in the U.S. suggest that release of the synthetic sex pheromone of L. serricorne can significantly inhibit proper orientation of male cigarette beetles to females and results in reduced reproduction.

Influence of interspecific competition between stored products pests on biological control with parasitoids

Jeongyeon Ji[1], Youngwoo Nam[2], Mun Il Ryoo[3]

[1]Animal, Plant and Fisheries Quarantine and Inspection Agency, Republic of Korea, [2]Korea Forest Research Institute, Republic of Korea, [3]Korea University, Republic of Korea

Interspecific competition between pest species sharing common resources would be an important factor in suppression efficiency by their parasitoids because the efficiency could be modified by the competition between the pests or by the interaction with the other parasitoid. In this study, to evaluate the influences of the competition on biological control with parasitoids, five combinations were used to test the influences: 1) single population of rice weevil and Indian meal moth 2) mixed population of rice weevil and Indian meal moth 3) the mixed population under A. calandrae 4) the mixed population under B. hebetor and 5) the mixed population under both parasitoids. In mixed population of rice weevil and Indian meal moth, the interspecific competition between rice weevil and Indian meal moth affected the moth population positively, but negatively the rice weevil population, suggesting that indian meal moth has higher competition ability on both resource use and interference competition than rice weevil. A. calandrae or B. hebetor alone could not change the population dynamics of the two competing pests with similar densities of the rice weevil and Indian meal moth as those without the parasitoids. When both parasitoids occurred together in the mixed populations, the population dynamics of the rice weevil and Indian meal moth were more stable than in the other combinations with significantly lower density level, which could be due to the changes in the spatial coincidence caused by the interspecific interaction between the two parasitoids.
